Introduction

This Summary for Policymakers (SPM) presents key findings of the Working Group I (WGI) contribution to the IPCC's Sixth Assessment Report (AR6)[1] on the physical science basis of climate change. The report builds upon the 2013 Working Group I contribution to the IPCC's Fifth Assessment Report (AR5) and the 2018–2019 IPCC Special Reports[2] of the AR6 cycle and incorporates subsequent new evidence from climate science[3].

This SPM provides a high-level summary of the understanding of the current state of the climate, including how it is changing and the role of human influence, the state of knowledge about possible climate futures, climate information relevant to regions and sectors, and limiting human-induced climate change.

Based on scientific understanding, key findings can be formulated as statements of fact or associated with an assessed level of confidence indicated using the IPCC calibrated language[4].

The scientific basis for each key finding is found in chapter sections of the main Report, and in the integrated synthesis presented in the Technical Summary (hereafter TS), and is indicated in curly brackets. The AR6 WGI Interactive Atlas facilitates exploration of these key synthesis findings, and supporting climate change information, across the WGI reference regions[5].

[1] Decision IPCC/XLVI-2.

[2] The three Special reports are: Global warming of 1.5°C: an IPCC Special Report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty (SR1.5); Climate Change and Land: an IPCC Special Report on climate change, desertification, land degradation, sustainable land management, food security, and greenhouse gas fluxes in terrestrial ecosystems (SRCCL); IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC).

[3] The assessment covers scientific literature accepted for publication by 31 January 2021.

[4] Each finding is grounded in an evaluation of underlying evidence and agreement. A level of confidence is expressed using five qualifiers: very low, low, medium, high and very high, and typeset in italics, for example, *medium confidence*. The following terms have been used to indicate the assessed likelihood of an outcome or a result: *virtually certain* 99–100% probability, *very likely* 90–100%, *likely* 66–100%, *about as likely as not* 33–66%, *unlikely* 0–33%, *very unlikely* 0–10%, *exceptionally unlikely* 0–1%. Additional terms (*extremely likely* 95–100%, *more likely than not* >50–100%, and *extremely unlikely* 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, for example, *very likely*. This is consistent with AR5. In this Report, unless stated otherwise, square brackets [x to y] are used to provide the assessed *very likely* range, or 90% interval.

[5] The Interactive Atlas is available at https://interactive-atlas.ipcc.ch

A. The Current State of the Climate

Since AR5, improvements in observationally based estimates and information from paleoclimate archives provide a comprehensive view of each component of the climate system and its changes to date. New climate model simulations, new analyses, and methods combining multiple lines of evidence lead to improved understanding of human influence on a wider range of climate variables, including weather and climate extremes. The time periods considered throughout this Section depend upon the availability of observational products, paleoclimate archives and peer-reviewed studies.

A.1 It is unequivocal that human influence has warmed the atmosphere, ocean and land. Widespread and rapid changes in the atmosphere, ocean, cryosphere and biosphere have occurred.

{2.2, 2.3, Cross-Chapter Box 2.3, 3.3, 3.4, 3.5, 3.6, 3.8, 5.2, 5.3, 6.4, 7.3, 8.3, 9.2, 9.3, 9.5, 9.6, Cross-Chapter Box 9.1} **(Figure SPM.1, Figure SPM.2)**

A.1.1 Observed increases in well-mixed greenhouse gas (GHG) concentrations since around 1750 are unequivocally caused by human activities. Since 2011 (measurements reported in AR5), concentrations have continued to increase in the atmosphere, reaching annual averages of 410 ppm for carbon dioxide (CO_2), 1866 ppb for methane (CH_4), and 332 ppb for nitrous oxide (N_2O) in 2019[6]. Land and ocean have taken up a near-constant proportion (globally about 56% per year) of CO_2 emissions from human activities over the past six decades, with regional differences (*high confidence*)[7]. {2.2, 5.2, 7.3, TS.2.2, Box TS.5}

A.1.2 Each of the last four decades has been successively warmer than any decade that preceded it since 1850. Global surface temperature[8] in the first two decades of the 21st century (2001-2020) was 0.99 [0.84-1.10] °C higher than 1850-1900[9]. Global surface temperature was 1.09 [0.95 to 1.20] °C higher in 2011–2020 than 1850–1900, with larger increases over land (1.59 [1.34 to 1.83] °C) than over the ocean (0.88 [0.68 to 1.01] °C). The estimated increase in global surface temperature since AR5 is principally due to further warming since 2003–2012 (+0.19 [0.16 to 0.22] °C). Additionally, methodological advances and new datasets contributed approximately 0.1ºC to the updated estimate of warming in AR6[10].

[6] Other GHG concentrations in 2019 were: PFCs (109 ppt CF_4 equivalent); SF_6 (10 ppt); NF_3 (2 ppt); HFCs (237 ppt HFC-134a equivalent); other Montreal Protocol gases (mainly CFCs, HCFCs, 1032 ppt CFC-12 equivalent). Increases from 2011 are 19 ppm for CO_2, 63 ppb for CH_4 and 8 ppb for N_2O.

[7] Land and ocean are not substantial sinks for other GHGs.

[8] The term 'global surface temperature' is used in reference to both global mean surface temperature and global surface air temperature throughout this SPM. Changes in these quantities are assessed with *high confidence* to differ by at most 10% from one another, but conflicting lines of evidence lead to *low confidence* in the sign of any difference in long-term trend. {Cross-Section Box TS.1}

[9] The period 1850–1900 represents the earliest period of sufficiently globally complete observations to estimate global surface temperature and, consistent with AR5 and SR1.5, is used as an approximation for pre-industrial conditions.

[10] Since AR5, methodological advances and new datasets have provided a more complete spatial representation of changes in surface temperature, including in the Arctic. These and other improvements have additionally increased the estimate of global surface temperature change by approximately 0.1 ºC, but this increase does not represent additional physical warming since the AR5.

A.1.3 The *likely* range of total human-caused global surface temperature increase from 1850–1900 to 2010–2019[11] is 0.8°C to 1.3°C, with a best estimate of 1.07°C. It is *likely* that well-mixed GHGs contributed a warming of 1.0°C to 2.0°C, other human drivers (principally aerosols) contributed a cooling of 0.0°C to 0.8°C, natural drivers changed global surface temperature by –0.1°C to 0.1°C, and internal variability changed it by –0.2°C to 0.2°C. It is *very likely* that well-mixed GHGs were the main driver[12] of tropospheric warming since 1979, and *extremely likely* that human-caused stratospheric ozone depletion was the main driver of cooling of the lower stratosphere between 1979 and the mid-1990s.
{3.3, 6.4, 7.3, Cross-Section Box TS.1, TS.2.3} **(Figure SPM.2)**

A.1.4 Globally averaged precipitation over land has *likely* increased since 1950, with a faster rate of increase since the 1980s (*medium confidence*). It is *likely* that human influence contributed to the pattern of observed precipitation changes since the mid-20th century, and *extremely likely* that human influence contributed to the pattern of observed changes in near-surface ocean salinity. Mid-latitude storm tracks have *likely* shifted poleward in both hemispheres since the 1980s, with marked seasonality in trends (*medium confidence*). For the Southern Hemisphere, human influence *very likely* contributed to the poleward shift of the closely related extratropical jet in austral summer.
{2.3, 3.3, 8.3, 9.2, TS.2.3, TS.2.4, Box TS.6}

A.1.5 Human influence is *very likely* the main driver of the global retreat of glaciers since the 1990s and the decrease in Arctic sea ice area between 1979–1988 and 2010–2019 (about 40% in September and about 10% in March). There has been no significant trend in Antarctic sea ice area from 1979 to 2020 due to regionally opposing trends and large internal variability. Human influence *very likely* contributed to the decrease in Northern Hemisphere spring snow cover since 1950. It is *very likely* that human influence has contributed to the observed surface melting of the Greenland Ice Sheet over the past two decades, but there is only *limited evidence*, with *medium agreement*, of human influence on the Antarctic Ice Sheet mass loss.
{2.3, 3.4, 8.3, 9.3, 9.5, TS.2.5}

A.1.6 It is *virtually certain* that the global upper ocean (0–700 m) has warmed since the 1970s and *extremely likely* that human influence is the main driver. It is *virtually certain* that human-caused CO_2 emissions are the main driver of current global acidification of the surface open ocean. There is *high confidence* that oxygen levels have dropped in many upper ocean regions since the mid-20th century, and *medium confidence* that human influence contributed to this drop.
{2.3, 3.5, 3.6, 5.3, 9.2, TS.2.4}

A.1.7 Global mean sea level increased by 0.20 [0.15 to 0.25] m between 1901 and 2018. The average rate of sea level rise was 1.3 [0.6 to 2.1] mm yr^{-1} between 1901 and 1971, increasing to 1.9 [0.8 to 2.9] mm yr^{-1} between 1971 and 2006, and further increasing to 3.7 [3.2 to 4.2] mm yr^{-1} between 2006 and 2018 (*high confidence*). Human influence was *very likely* the main driver of these increases since at least 1971.
{2.3, 3.5, 9.6, Cross-Chapter Box 9.1, Box TS.4}

A.1.8 Changes in the land biosphere since 1970 are consistent with global warming: climate zones have shifted poleward in both hemispheres, and the growing season has on average lengthened by up to two days per decade since the 1950s in the Northern Hemisphere extratropics (*high confidence*).
{2.3, TS.2.6}

[11] The period distinction with A.1.2 arises because the attribution studies consider this slightly earlier period. The observed warming to 2010–2019 is 1.06 [0.88 to 1.21] °C.

[12] Throughout this SPM, 'main driver' means responsible for more than 50% of the change.

Human influence has warmed the climate at a rate that is unprecedented in at least the last 2000 years

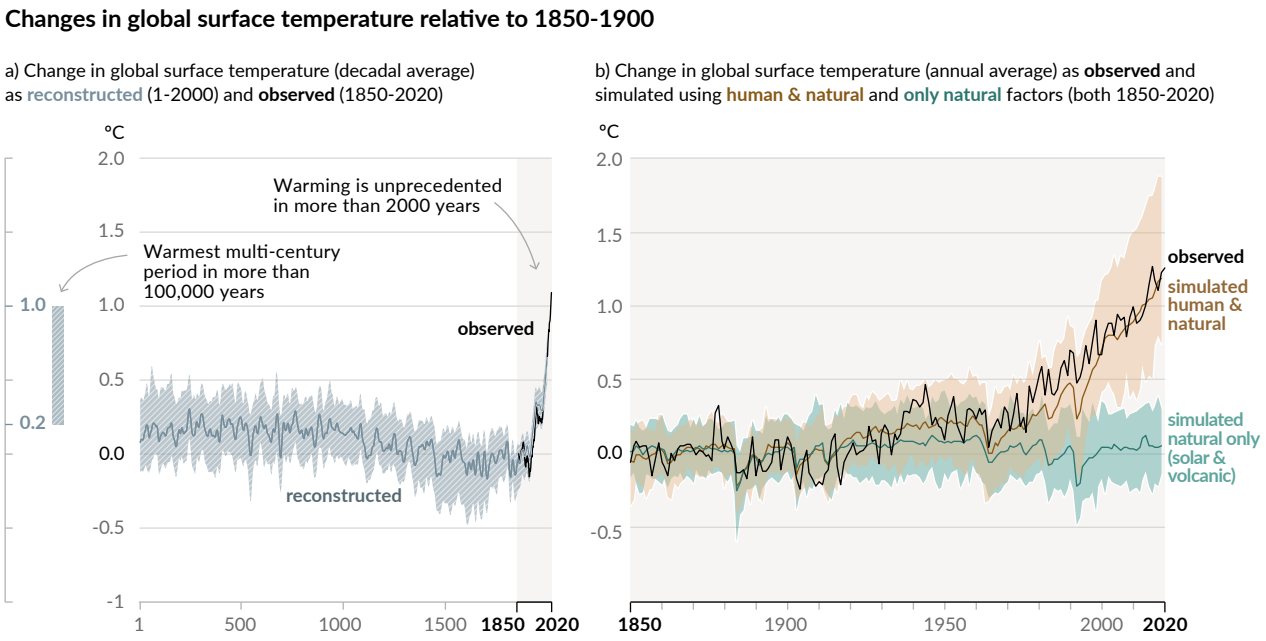

Figure SPM.1: History of global temperature change and causes of recent warming.

Panel a): Changes in global surface temperature reconstructed from paleoclimate archives (solid grey line, 1–2000) **and from direct observations** (solid black line, 1850–2020), both relative to 1850–1900 and decadally averaged. The vertical bar on the left shows the estimated temperature (*very likely* range) during the warmest multi-century period in at least the last 100,000 years, which occurred around 6500 years ago during the current interglacial period (Holocene). The Last Interglacial, around 125,000 years ago, is the next most recent candidate for a period of higher temperature. These past warm periods were caused by slow (multi-millennial) orbital variations. The grey shading with white diagonal lines shows the *very likely* ranges for the temperature reconstructions.

Panel b): Changes in global surface temperature over the past 170 years (black line) relative to 1850–1900 and annually averaged, compared to CMIP6 climate model simulations (see Box SPM.1) of the temperature response to both human and natural drivers (brown), and to only natural drivers (solar and volcanic activity, green). Solid coloured lines show the multi-model average, and coloured shades show the *very likely* range of simulations. (see Figure SPM.2 for the assessed contributions to warming).

{2.3.1, 3.3, Cross-Chapter Box 2.3, Cross-Section Box TS.1, Figure 1a, TS.2.2}

Observed warming is driven by emissions from human activities, with greenhouse gas warming partly masked by aerosol cooling

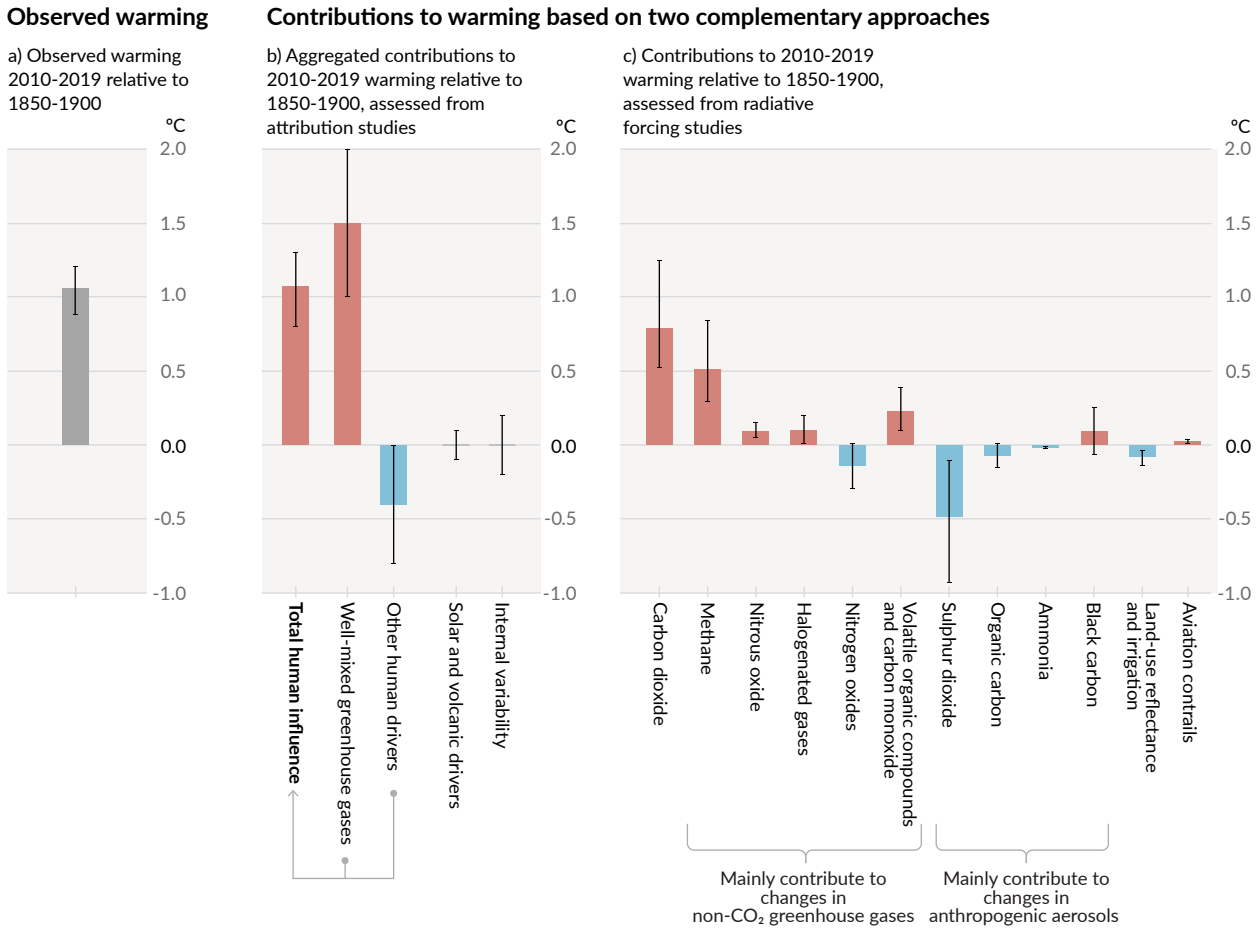

Figure SPM.2: Assessed contributions to observed warming in 2010–2019 relative to 1850–1900.

Panel a): Observed global warming (increase in global surface temperature) and its *very likely* range {3.3.1, Cross-Chapter Box 2.3}.

Panel b): Evidence from attribution studies, which synthesize information from climate models and observations. The panel shows temperature change attributed to total human influence, changes in well-mixed greenhouse gas concentrations, other human drivers due to aerosols, ozone and land-use change (land-use reflectance), solar and volcanic drivers, and internal climate variability. Whiskers show *likely* ranges {3.3.1}.

Panel c): Evidence from the assessment of radiative forcing and climate sensitivity. The panel shows temperature changes from individual components of human influence, including emissions of greenhouse gases, aerosols and their precursors; land-use changes (land-use reflectance and irrigation); and aviation contrails. Whiskers show *very likely* ranges. Estimates account for both direct emissions into the atmosphere and their effect, if any, on other climate drivers. For aerosols, both direct (through radiation) and indirect (through interactions with clouds) effects are considered.{6.4.2, 7.3}

A.2 The scale of recent changes across the climate system as a whole and the present state of many aspects of the climate system are unprecedented over many centuries to many thousands of years.

{Cross-Chapter Box 2.1, 2.2, 2.3, 5.1} **(Figure SPM.1)**

A.2.1 In 2019, atmospheric CO_2 concentrations were higher than at any time in at least 2 million years (*high confidence)*, and concentrations of CH_4 and N_2O were higher than at any time in at least 800,000 years (*very high confidence*). Since 1750, increases in CO_2 (47%) and CH_4 (156%) concentrations far exceed, and increases in N_2O (23%) are similar to, the natural multi-millennial changes between glacial and interglacial periods over at least the past 800,000 years (*very high confidence*).
{2.2, 5.1, TS.2.2}

A.2.2 Global surface temperature has increased faster since 1970 than in any other 50-year period over at least the last 2000 years (*high confidence*). Temperatures during the most recent decade (2011–2020) exceed those of the most recent multi-century warm period, around 6500 years ago[13] [0.2°C to 1°C relative to 1850–1900] (*medium confidence*). Prior to that, the next most recent warm period was about 125,000 years ago when the multi-century temperature [0.5°C to 1.5°C relative to 1850–1900] overlaps the observations of the most recent decade (*medium confidence*).
{Cross-Chapter Box 2.1, 2.3, Cross-Section Box TS.1} **(Figure SPM.1)**

A.2.3 In 2011–2020, annual average Arctic sea ice area reached its lowest level since at least 1850 (*high confidence*). Late summer Arctic sea ice area was smaller than at any time in at least the past 1000 years (*medium confidence*). The global nature of glacier retreat, with almost all of the world's glaciers retreating synchronously, since the 1950s is unprecedented in at least the last 2000 years (*medium confidence*).
{2.3, TS.2.5}

A.2.4 Global mean sea level has risen faster since 1900 than over any preceding century in at least the last 3000 years (*high confidence*). The global ocean has warmed faster over the past century than since the end of the last deglacial transition (around 11,000 years ago) (*medium confidence*). A long-term increase in surface open ocean pH occurred over the past 50 million years (*high confidence*), and surface open ocean pH as low as recent decades is unusual in the last 2 million years (*medium confidence*).
{2.3, TS.2.4, Box TS.4}

[13] As stated in section B.1, even under the very low emissions scenario SSP1-1.9, temperatures are assessed to remain elevated above those of the most recent decade until at least 2100 and therefore warmer than the century-scale period 6500 years ago.

A.3 Human-induced climate change is already affecting many weather and climate extremes in every region across the globe. Evidence of observed changes in extremes such as heatwaves, heavy precipitation, droughts, and tropical cyclones, and, in particular, their attribution to human influence, has strengthened since AR5.

{2.3, 3.3, 8.2, 8.3, 8.4, 8.5, 8.6, Box 8.1, Box 8.2, Box 9.2, 10.6, 11.2, 11.3, 11.4, 11.6, 11.7, 11.8, 11.9, 12.3} **(Figure SPM.3)**

A.3.1 It is *virtually certain* that hot extremes (including heatwaves) have become more frequent and more intense across most land regions since the 1950s, while cold extremes (including cold waves) have become less frequent and less severe, with *high confidence* that human-induced climate change is the main driver[14] of these changes. Some recent hot extremes observed over the past decade would have been *extremely unlikely* to occur without human influence on the climate system. Marine heatwaves have approximately doubled in frequency since the 1980s (*high confidence*), and human influence has *very likely* contributed to most of them since at least 2006.
{Box 9.2, 11.2, 11.3, 11.9, TS.2.4, TS.2.6, Box TS.10} **(Figure SPM.3)**

A.3.2 The frequency and intensity of heavy precipitation events have increased since the 1950s over most land area for which observational data are sufficient for trend analysis (*high confidence*), and human-induced climate change is *likely* the main driver. Human-induced climate change has contributed to increases in agricultural and ecological droughts[15] in some regions due to increased land evapotranspiration[16] (*medium confidence*).
{8.2, 8.3, 11.4, 11.6, 11.9, TS.2.6, Box TS.10} **(Figure SPM.3)**

A.3.3 Decreases in global land monsoon precipitation[17] from the 1950s to the 1980s are partly attributed to human-caused Northern Hemisphere aerosol emissions, but increases since then have resulted from rising GHG concentrations and decadal to multi-decadal internal variability (*medium confidence*). Over South Asia, East Asia and West Africa increases in monsoon precipitation due to warming from GHG emissions were counteracted by decreases in monsoon precipitation due to cooling from human-caused aerosol emissions over the 20th century (*high confidence*). Increases in West African monsoon precipitation since the 1980s are partly due to the growing influence of GHGs and reductions in the cooling effect of human-caused aerosol emissions over Europe and North America (*medium confidence*).
{2.3, 3.3, 8.2, 8.3, 8.4, 8.5, 8.6, Box 8.1, Box 8.2, 10.6, Box TS.13}

[14] Throughout this SPM, 'main driver' means responsible for more than 50% of the change.

[15] Agricultural and ecological drought (depending on the affected biome): a period with abnormal soil moisture deficit, which results from combined shortage of precipitation and excess evapotranspiration, and during the growing season impinges on crop production or ecosystem function in general. Observed changes in meteorological droughts (precipitation deficits) and hydrological droughts (streamflow deficits) are distinct from those in agricultural and ecological droughts and addressed in the underlying AR6 material (Chapter 11).

[16] The combined processes through which water is transferred to the atmosphere from open water and ice surfaces, bare soil, and vegetation that make up the Earth's surface.

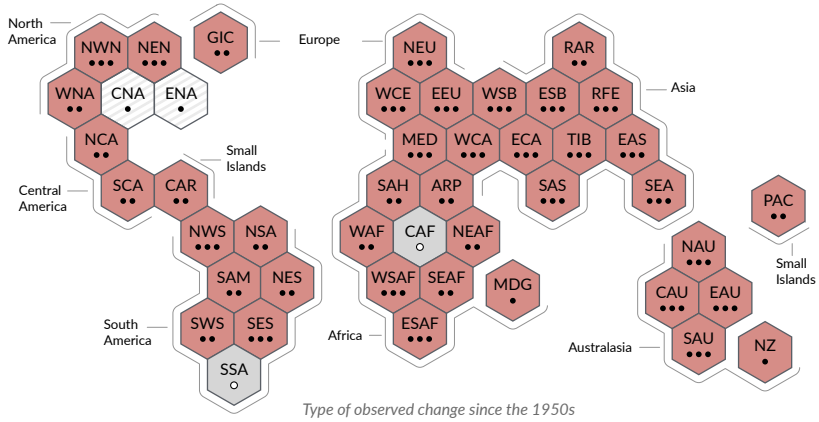
[17] The global monsoon is defined as the area in which the annual range (local summer minus local winter) of precipitation is greater than 2.5 mm day^{-1}. Global land monsoon precipitation refers to the mean precipitation over land areas within the global monsoon.

A.3.4 It is *likely* that the global proportion of major (Category 3–5) tropical cyclone occurrence has increased over the last four decades, and the latitude where tropical cyclones in the western North Pacific reach their peak intensity has shifted northward; these changes cannot be explained by internal variability alone (*medium confidence*). There is *low confidence* in long-term (multi-decadal to centennial) trends in the frequency of all-category tropical cyclones. Event attribution studies and physical understanding indicate that human-induced climate change increases heavy precipitation associated with tropical cyclones (*high confidence*) but data limitations inhibit clear detection of past trends on the global scale. {8.2, 11.7, Box TS.10}

A.3.5 Human influence has *likely* increased the chance of compound extreme events[18] since the 1950s. This includes increases in the frequency of concurrent heatwaves and droughts on the global scale (*high confidence*); fire weather in some regions of all inhabited continents (*medium confidence*); and compound flooding in some locations (*medium confidence*). {11.6, 11.7, 11.8, 12.3, 12.4, TS.2.6, Table TS.5, Box TS.10}

[18] Compound extreme events are the combination of multiple drivers and/or hazards that contribute to societal or environmental risk. Examples are concurrent heatwaves and droughts, compound flooding (e.g., a storm surge in combination with extreme rainfall and/or river flow), compound fire weather conditions (i.e., a combination of hot, dry, and windy conditions), or concurrent extremes at different locations.

Climate change is already affecting every inhabited region across the globe with human influence contributing to many observed changes in weather and climate extremes



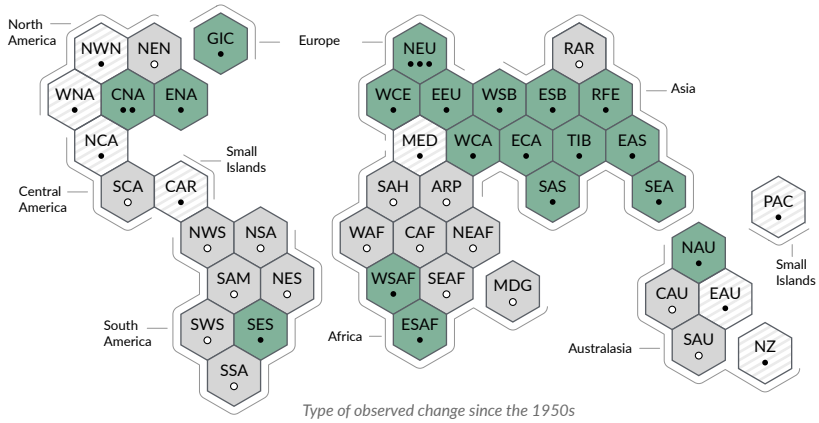
a) Synthesis of assessment of observed change in **hot extremes** and confidence in human contribution to the observed changes in the world's regions

Type of observed change in hot extremes

- Increase (41)
- Decrease (0)
- Low agreement in the type of change (2)
- Limited data and/or literature (2)

Confidence in human contribution to the observed change

- ●●● High
- ●● Medium
- ● Low due to limited agreement
- ○ Low due to limited evidence



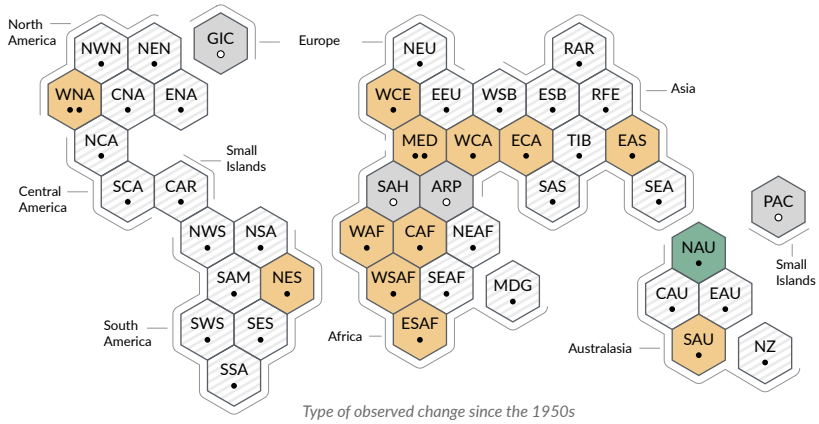
b) Synthesis of assessment of observed change in **heavy precipitation** and confidence in human contribution to the observed changes in the world's regions

Type of observed change in heavy precipitation

- Increase (19)
- Decrease (0)
- Low agreement in the type of change (8)
- Limited data and/or literature (18)

Confidence in human contribution to the observed change

- ●●● High
- ●● Medium
- ● Low due to limited agreement
- ○ Low due to limited evidence



c) Synthesis of assessment of observed change in **agricultural and ecological drought** and confidence in human contribution to the observed changes in the world's regions

Type of observed change in agricultural and ecological drought

- Increase (12)
- Decrease (1)
- Low agreement in the type of change (28)
- Limited data and/or literature (4)

Confidence in human contribution to the observed change

- ●●● High
- ●● Medium
- ● Low due to limited agreement
- ○ Low due to limited evidence

Each hexagon corresponds to one of the IPCC AR6 WGI reference regions

Figure SPM.3: Synthesis of assessed observed and attributable regional changes.

The IPCC AR6 WGI inhabited regions are displayed as **hexagons** with identical size in their approximate geographical location (see legend for regional acronyms). All assessments are made for each region as a whole and for the 1950s to the present. Assessments made on different time scales or more local spatial scales might differ from what is shown in the figure. The **colours** in each panel represent the four outcomes of the assessment on observed changes. White and light grey striped hexagons are used where there is *low agreement* in the type of change for the region as a whole, and grey hexagons are used when there is limited data and/or literature that prevents an assessment of the region as a whole. Other colours indicate at least *medium confidence* in the observed change. The **confidence level** for the human influence on these observed changes is based on assessing trend detection and attribution and event attribution literature, and it is indicated by the number of dots: three dots for *high confidence*, two dots for *medium confidence* and one dot for *low confidence* (filled: limited agreement; empty: limited evidence).

Panel a) For hot extremes, the evidence is mostly drawn from changes in metrics based on daily maximum temperatures; regional studies using other indices (heatwave duration, frequency and intensity) are used in addition. Red hexagons indicate regions where there is at least *medium confidence* in an observed increase in hot extremes.

Panel b) For heavy precipitation, the evidence is mostly drawn from changes in indices based on one-day or five-day precipitation amounts using global and regional studies. Green hexagons indicate regions where there is at least *medium confidence* in an observed increase in heavy precipitation.

Panel c) Agricultural and ecological droughts are assessed based on observed and simulated changes in total column soil moisture, complemented by evidence on changes in surface soil moisture, water balance (precipitation minus evapotranspiration) and indices driven by precipitation and atmospheric evaporative demand. Yellow hexagons indicate regions where there is at least *medium confidence* in an observed increase in this type of drought and green hexagons indicate regions where there is at least *medium confidence* in an observed decrease in agricultural and ecological drought.

For all regions, table TS.5 shows a broader range of observed changes besides the ones shown in this figure. Note that SSA is the only region that does not display observed changes in the metrics shown in this figure, but is affected by observed increases in mean temperature, decreases in frost, and increases in marine heatwaves.

{11.9, Table TS.5, Box TS.10, Figure 1, Atlas 1.3.3, Figure Atlas.2}

A.4 Improved knowledge of climate processes, paleoclimate evidence and the response of the climate system to increasing radiative forcing gives a best estimate of equilibrium climate sensitivity of 3°C with a narrower range compared to AR5. {2.2, 7.3, 7.4, 7.5, Box 7.2, Cross-Chapter Box 9.1, 9.4, 9.5, 9.6}

A.4.1 Human-caused radiative forcing of 2.72 [1.96 to 3.48] W m^{-2} in 2019 relative to 1750 has warmed the climate system. This warming is mainly due to increased GHG concentrations, partly reduced by cooling due to increased aerosol concentrations. The radiative forcing has increased by 0.43 W m^{-2} (19%) relative to AR5, of which 0.34 W m^{-2} is due to the increase in GHG concentrations since 2011. The remainder is due to improved scientific understanding and changes in the assessment of aerosol forcing, which include decreases in concentration and improvement in its calculation (*high confidence*).
{2.2, 7.3, TS.2.2, TS.3.1}

A.4.2 Human-caused net positive radiative forcing causes an accumulation of additional energy (heating) in the climate system, partly reduced by increased energy loss to space in response to surface warming. The observed average rate of heating of the climate system increased from 0.50 [0.32 to 0.69] W m^{-2} for the period 1971–2006[19], to 0.79 [0.52 to 1.06] W m^{-2} for the period 2006–2018[20] (*high confidence*). Ocean warming accounted for 91% of the heating in the climate system, with land warming, ice loss and atmospheric warming accounting for about 5%, 3% and 1%, respectively (*high confidence*).
{7.2, Box 7.2, TS.3.1}

A.4.3 Heating of the climate system has caused global mean sea level rise through ice loss on land and thermal expansion from ocean warming. Thermal expansion explained 50% of sea level rise during 1971–2018, while ice loss from glaciers contributed 22%, ice sheets 20% and changes in land water storage 8%. The rate of ice sheet loss increased by a factor of four between 1992–1999 and 2010–2019. Together, ice sheet and glacier mass loss were the dominant contributors to global mean sea level rise during 2006-2018. (*high confidence*)
{Cross-Chapter Box 9.1, 9.4, 9.5, 9.6}

A.4.4 The equilibrium climate sensitivity is an important quantity used to estimate how the climate responds to radiative forcing. Based on multiple lines of evidence[21], the *very likely* range of equilibrium climate sensitivity is between 2°C (*high confidence*) and 5°C (*medium confidence*). The AR6 assessed best estimate is 3°C with a *likely* range of 2.5°C to 4°C (*high confidence*), compared to 1.5°C to 4.5°C in AR5, which did not provide a best estimate.
{7.4, 7.5, TS.3.2}

[19] cumulative energy increase of 282 [177 to 387] ZJ over 1971–2006 (1 ZJ = 10^{21} J).

[20] cumulative energy increase of 152 [100 to 205] ZJ over 2006–2018.

[21] Understanding of climate processes, the instrumental record, paleoclimates and model-based emergent constraints (see glossary).

B. Possible Climate Futures

A set of five new illustrative emissions scenarios is considered consistently across this report to explore the climate response to a broader range of greenhouse gas (GHG), land use and air pollutant futures than assessed in AR5. This set of scenarios drives climate model projections of changes in the climate system. These projections account for solar activity and background forcing from volcanoes. Results over the 21st century are provided for the near-term (2021–2040), mid-term (2041–2060) and long-term (2081–2100) relative to 1850–1900, unless otherwise stated.

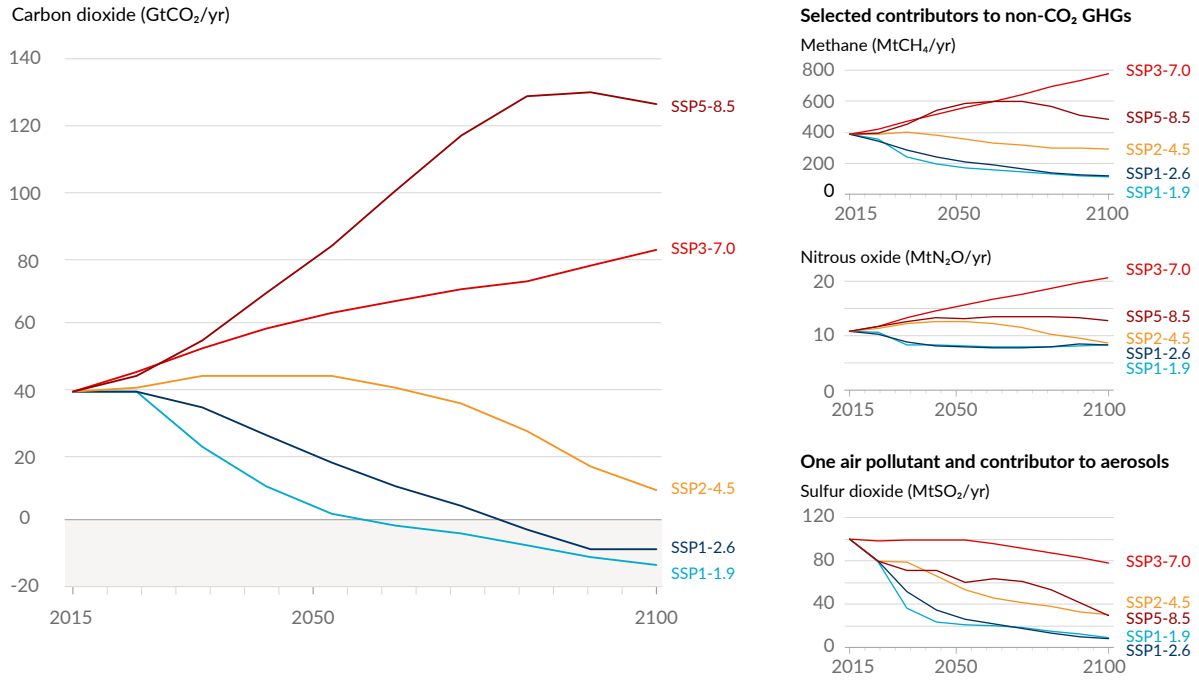
Box SPM.1: Scenarios, Climate Models and Projections

Box SPM.1.1: This report assesses the climate response to five illustrative scenarios that cover the range of possible future development of anthropogenic drivers of climate change found in the literature. They start in 2015, and include scenarios[22] with high and very high GHG emissions (SSP3-7.0 and SSP5-8.5) and CO_2 emissions that roughly double from current levels by 2100 and 2050, respectively, scenarios with intermediate GHG emissions (SSP2-4.5) and CO_2 emissions remaining around current levels until the middle of the century, and scenarios with very low and low GHG emissions and CO_2 emissions declining to net zero around or after 2050, followed by varying levels of net negative CO_2 emissions[23] (SSP1-1.9 and SSP1-2.6) as illustrated in Figure SPM.4. Emissions vary between scenarios depending on socio-economic assumptions, levels of climate change mitigation and, for aerosols and non-methane ozone precursors, air pollution controls. Alternative assumptions may result in similar emissions and climate responses, but the socio-economic assumptions and the feasibility or likelihood of individual scenarios is not part of the assessment.
{TS.1.3, 1.6, Cross-Chapter Box 1.4} **(Figure SPM.4)**

Box SPM.1.2: This report assesses results from climate models participating in the Coupled Model Intercomparison Project Phase 6 (CMIP6) of the World Climate Research Programme. These models include new and better representation of physical, chemical and biological processes, as well as higher resolution, compared to climate models considered in previous IPCC assessment reports. This has improved the simulation of the recent mean state of most large-scale indicators of climate change and many other aspects across the climate system. Some differences from observations remain, for example in regional precipitation patterns. The CMIP6 historical simulations assessed in this report have an ensemble mean global surface temperature change within 0.2°C of the observations over most of the historical period, and observed warming is within the *very likely* range of the CMIP6 ensemble. However, some CMIP6 models simulate a warming that is either above or below the assessed *very likely* range of observed warming.
{1.5, Cross-Chapter Box 2.2, 3.3, 3.8, TS.1.2, Cross-Section Box TS.1} (Figure SPM.1 b, Figure SPM.2)

Box SPM.1.3: The CMIP6 models considered in this Report have a wider range of climate sensitivity than in CMIP5 models and the AR6 assessed *very likely* range, which is based on multiple lines of evidence. These CMIP6 models also show a higher average climate sensitivity than CMIP5 and the AR6 assessed best estimate. The higher CMIP6 climate sensitivity values compared to CMIP5 can be traced to an amplifying cloud feedback that is larger in CMIP6 by about 20%.
{Box 7.1, 7.3, 7.4, 7.5, TS.3.2}

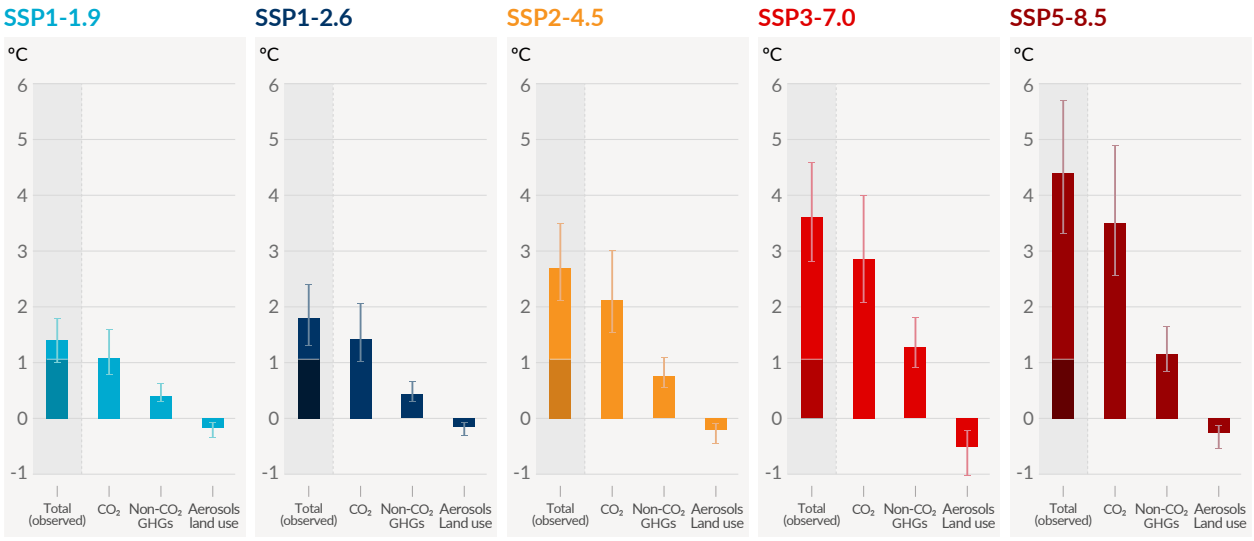
Box SPM.1.4: For the first time in an IPCC report, assessed future changes in global surface temperature, ocean warming and sea level are constructed by combining multi-model projections with observational constraints based on past simulated warming, as well as the AR6 assessment of climate sensitivity. For other quantities, such robust methods do not yet exist to constrain the projections. Nevertheless, robust projected



[22] Throughout this report, the five illustrative scenarios are referred to as SSPx-y, where 'SSPx' refers to the Shared Socio-economic Pathway or 'SSP' describing the socio-economic trends underlying the scenario, and 'y' refers to the approximate level of radiative forcing (in W m^{-2}) resulting from the scenario in the year 2100. A detailed comparison to scenarios used in earlier IPCC reports is provided in Section TS1.3 and 1.6 and 4.6. The SSPs that underlie the specific forcing scenarios used to drive climate models are not assessed by WGI. Rather, the SSPx-y labelling ensures traceability to the underlying literature in which specific forcing pathways are used as input to the climate models. IPCC is neutral with regard to the assumptions underlying the SSPs, which do not cover all possible scenarios. Alternative scenarios may be considered or developed.

[23] Net negative CO_2 emissions are reached when anthropogenic removals of CO_2 exceed anthropogenic emissions. {Glossary}

geographical patterns of many variables can be identified at a given level of global warming, common to all scenarios considered and independent of timing when the global warming level is reached.
{1.6, Box 4.1, 4.3, 4.6, 7.5, 9.2, 9.6, Cross-Chapter Box 11.1, Cross-Section Box TS.1}



Future emissions cause future additional warming, with total warming dominated by past and future CO_2 emissions

a) Future annual emissions of CO_2 (left) and of a subset of key non-CO_2 drivers (right), across five illustrative scenarios

b) Contribution to global surface temperature increase from different emissions, with a dominant role of CO_2 emissions

Change in global surface temperature in 2081-2100 relative to 1850-1900 (°C)

Total warming (observed warming to date in darker shade), warming from CO_2, warming from non-CO_2 GHGs and cooling from changes in aerosols and land use

Figure SPM.4: Future anthropogenic emissions of key drivers of climate change and warming contributions by groups of drivers for the five illustrative scenarios used in this report.

The five scenarios are SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5.

Panel a) Annual anthropogenic (human-caused) emissions over the 2015–2100 period. Shown are emissions trajectories for carbon dioxide (CO_2) from all sectors ($GtCO_2$/yr) (left graph) and for a subset of three key non-CO_2 drivers considered in the scenarios: methane (CH_4, $MtCH_4$/yr, top-right graph), nitrous oxide (N_2O, MtN_2O/yr, middle-right graph) and sulfur dioxide (SO_2, $MtSO_2$/yr, bottom-right graph, contributing to anthropogenic aerosols in panel b).

Panel b) Warming contributions by groups of anthropogenic drivers and by scenario are shown as change in global surface temperature (°C) in 2081–2100 relative to 1850–1900, with indication of the observed warming to date. Bars and whiskers represent median values and the *very likely* range, respectively. Within each scenario bar plot, the bars represent total global warming (°C; total bar) (see Table SPM.1) and warming contributions (°C) from changes in CO_2 (CO_2 bar), from non-CO_2 greenhouse gases (non-CO_2 GHGs bar; comprising well-mixed greenhouse gases and ozone) and net cooling from other anthropogenic drivers (aerosols and land-use bar; anthropogenic aerosols, changes in reflectance due to land-use and irrigation changes, and contrails from aviation; see Figure SPM.2, panel c, for the warming contributions to date for individual drivers). The best estimate for observed warming in 2010–2019 relative to 1850–1900 (see Figure SPM.2, panel a) is indicated in the darker column in the total bar. Warming contributions in panel b are calculated as explained in Table SPM.1 for the total bar. For the other bars the contribution by groups of drivers are calculated with a physical climate emulator of global surface temperature which relies on climate sensitivity and radiative forcing assessments.

{Cross-Chapter Box 1.4, 4.6, Figure 4.35, 6.7, Figure 6.18, 6.22 and 6.24, Cross-Chapter Box 7.1, 7.3, Figure 7.7, Box TS.7, Figures TS.4 and TS.15}

B.1 Global surface temperature will continue to increase until at least the mid-century under all emissions scenarios considered. Global warming of 1.5°C and 2°C will be exceeded during the 21st century unless deep reductions in CO_2 and other greenhouse gas emissions occur in the coming decades.

{2.3, Cross-Chapter Box 2.3, Cross-Chapter Box 2.4, 4.3, 4.4, 4.5} **(Figure SPM.1, Figure SPM.4, Figure SPM.8, Table SPM.1, Box SPM.1)**

B.1.1 Compared to 1850–1900, global surface temperature averaged over 2081–2100 is *very likely* to be higher by 1.0°C to 1.8°C under the very low GHG emissions scenario considered (SSP1-1.9), by 2.1°C to 3.5°C in the intermediate scenario (SSP2-4.5) and by 3.3°C to 5.7°C under the very high GHG emissions scenario (SSP5-8.5)[24]. The last time global surface temperature was sustained at or above 2.5°C higher than 1850–1900 was over 3 million years ago (*medium confidence*).
{2.3, Cross-Chapter Box 2.4, 4.3, 4.5, Box TS.2, Box TS.4, Cross-Section Box TS.1} **(Table SPM.1)**

Table SPM.1: Changes in global surface temperature, which are assessed based on multiple lines of evidence, for selected 20-year time periods and the five illustrative emissions scenarios considered. Temperature differences relative to the average global surface temperature of the period 1850–1900 are reported in °C. This includes the revised assessment of observed historical warming for the AR5 reference period 1986–2005, which in AR6 is higher by 0.08 [–0.01 to 0.12] °C than in the AR5 (see footnote 10). Changes relative to the recent reference period 1995–2014 may be calculated approximately by subtracting 0.85°C, the best estimate of the observed warming from 1850–1900 to 1995–2014.
{Cross-Chapter Box 2.3, 4.3, 4.4, Cross-Section Box TS.1}

[24] Changes in global surface temperature are reported as running 20-year averages, unless stated otherwise.

	Near term, 2021–2040		Mid-term, 2041–2060		Long term, 2081–2100	
Scenario	Best estimate (°C)	*Very likely* range (°C)	Best estimate (°C)	*Very likely* range (°C)	Best estimate (°C)	*Very likely* range (°C)
SSP1-1.9	1.5	1.2 to 1.7	1.6	1.2 to 2.0	1.4	1.0 to 1.8
SSP1-2.6	1.5	1.2 to 1.8	1.7	1.3 to 2.2	1.8	1.3 to 2.4
SSP2-4.5	1.5	1.2 to 1.8	2.0	1.6 to 2.5	2.7	2.1 to 3.5
SSP3-7.0	1.5	1.2 to 1.8	2.1	1.7 to 2.6	3.6	2.8 to 4.6
SSP5-8.5	1.6	1.3 to 1.9	2.4	1.9 to 3.0	4.4	3.3 to 5.7

B.1.2 Based on the assessment of multiple lines of evidence, global warming of 2°C, relative to 1850–1900, would be exceeded during the 21st century under the high and very high GHG emissions scenarios considered in this report (SSP3-7.0 and SSP5-8.5, respectively). Global warming of 2°C would *extremely likely* be exceeded in the intermediate scenario (SSP2-4.5). Under the very low and low GHG emissions scenarios, global warming of 2°C is *extremely unlikely* to be exceeded (SSP1-1.9), or *unlikely* to be exceeded (SSP1-2.6)[25]. Crossing the 2°C global warming level in the mid-term period (2041–2060) is *very likely* to occur under the very high GHG emissions scenario (SSP5-8.5), *likely* to occur under the high GHG emissions scenario (SSP3-7.0), and *more likely than not* to occur in the intermediate GHG emissions scenario (SSP2-4.5)[26].
{4.3, Cross-Section Box TS.1} **(Table SPM.1, Figure SPM.4, Box SPM.1)**

B.1.3 Global warming of 1.5°C relative to 1850-1900 would be exceeded during the 21st century under the intermediate, high and very high scenarios considered in this report (SSP2-4.5, SSP3-7.0 and SSP5-8.5, respectively). Under the five illustrative scenarios, in the near term (2021-2040), the 1.5°C global warming level is *very likely* to be exceeded under the very high GHG emissions scenario (SSP5-8.5), *likely* to be exceeded under the intermediate and high GHG emissions scenarios (SSP2-4.5 and SSP3-7.0), *more likely than not* to be exceeded under the low GHG emissions scenario (SSP1-2.6) and *more likely than not* to be reached under the very low GHG emissions scenario (SSP1-1.9)[27]. Furthermore, for the very low GHG emissions scenario (SSP1-1.9), it is *more likely than not* that global surface temperature would decline back to below 1.5°C toward the end of the 21st century, with a temporary overshoot of no more than 0.1°C above 1.5°C global warming.
{4.3, Cross-Section Box TS.1} **(Table SPM.1, Figure SPM.4)**

[25] SSP1-1.9 and SSP1-2.6 are scenarios that start in 2015 and have very low and low GHG emissions and CO_2 emissions declining to net zero around or after 2050, followed by varying levels of net negative CO_2 emissions.

[26] Crossing is defined here as having the assessed global surface temperature change, averaged over a 20-year period, exceed a particular global warming level.

[27] The AR6 assessment of when a given global warming level is first exceeded benefits from the consideration of the illustrative scenarios, the multiple lines of evidence entering the assessment of future global surface temperature response to radiative forcing, and the improved estimate of historical warming. The AR6 assessment is thus not directly comparable to the SR1.5 SPM, which reported likely reaching 1.5°C global warming between 2030 and 2052, from a simple linear extrapolation of warming rates of the recent past. When considering scenarios similar to SSP1-1.9 instead of linear extrapolation, the SR1.5 estimate of when 1.5°C global

B.1.4 Global surface temperature in any single year can vary above or below the long-term human-induced trend, due to substantial natural variability[28]. The occurrence of individual years with global surface temperature change above a certain level, for example 1.5°C or 2ºC, relative to 1850–1900 does not imply that this global warming level has been reached[29].
{Cross-Chapter Box 2.3, 4.3, 4.4, Box 4.1, Cross-Section Box TS.1} **(Table SPM.1, Figure SPM.1, Figure SPM.8)**

B.2 Many changes in the climate system become larger in direct relation to increasing global warming. They include increases in the frequency and intensity of hot extremes, marine heatwaves, and heavy precipitation, agricultural and ecological droughts in some regions, and proportion of intense tropical cyclones, as well as reductions in Arctic sea ice, snow cover and permafrost. {4.3, 4.5, 4.6, 7.4, 8.2, 8.4, Box 8.2, 9.3, 9.5, Box 9.2, 11.1, 11.2, 11.3, 11.4, 11.6, 11.7, 11.9, Cross-Chapter Box 11.1, 12.4, 12.5, Cross-Chapter Box 12.1, Atlas.4, Atlas.5, Atlas.6, Atlas.7, Atlas.8, Atlas.9, Atlas.10, Atlas.11} **(Figure SPM.5, Figure SPM.6, Figure SPM.8)**

B.2.1 It is *virtually certain* that the land surface will continue to warm more than the ocean surface (*likely* 1.4 to 1.7 times more). It is *virtually certain* that the Arctic will continue to warm more than global surface temperature, with *high confidence* above two times the rate of global warming.
{2.3, 4.3, 4.5, 4.6, 7.4, 11.1, 11.3, 11.9, 12.4, 12.5, Cross-Chapter Box 12.1, Atlas.4, Atlas.5, Atlas.6, Atlas.7, Atlas.8, Atlas.9, Atlas.10, Atlas.11, Cross-Section Box TS.1, TS.2.6} **(Figure SPM.5)**

B.2.2 With every additional increment of global warming, changes in extremes continue to become larger. For example, every additional 0.5°C of global warming causes clearly discernible increases in the intensity and frequency of hot extremes, including heatwaves (*very likely*), and heavy precipitation (*high confidence*), as well as agricultural and ecological droughts[30] in some regions (*high confidence*). Discernible changes in intensity and frequency of meteorological droughts, with more regions showing increases than decreases, are seen in some regions for every additional 0.5°C of global warming (*medium confidence*). Increases in frequency and intensity of hydrological droughts become larger with increasing global warming in some regions (*medium confidence*). There will be an increasing occurrence of some extreme events unprecedented in the observational record with additional global warming, even at 1.5°C of global warming. Projected percentage changes in frequency are higher for rarer events (*high confidence*).
{8.2, 11.2, 11.3, 11.4, 11.6, 11.9, Cross-Chapter Box 11.1, Cross-Chapter Box 12.1, TS.2.6} **(Figure SPM.5, Figure SPM.6)**

warming is first exceeded is close to the best estimate reported here.

[28] Natural variability refers to climatic fluctuations that occur without any human influence, that is, internal variability combined with the response to external natural factors such as volcanic eruptions, changes in solar activity and, on longer time scales, orbital effects and plate tectonics.

[29] The internal variability in any single year is estimated to be ± 0.25°C (5–95% range, *high confidence*).

[30] Projected changes in agricultural and ecological droughts are primarily assessed based on total column soil moisture. See footnote 15 for definition and relation to precipitation and evapotranspiration.

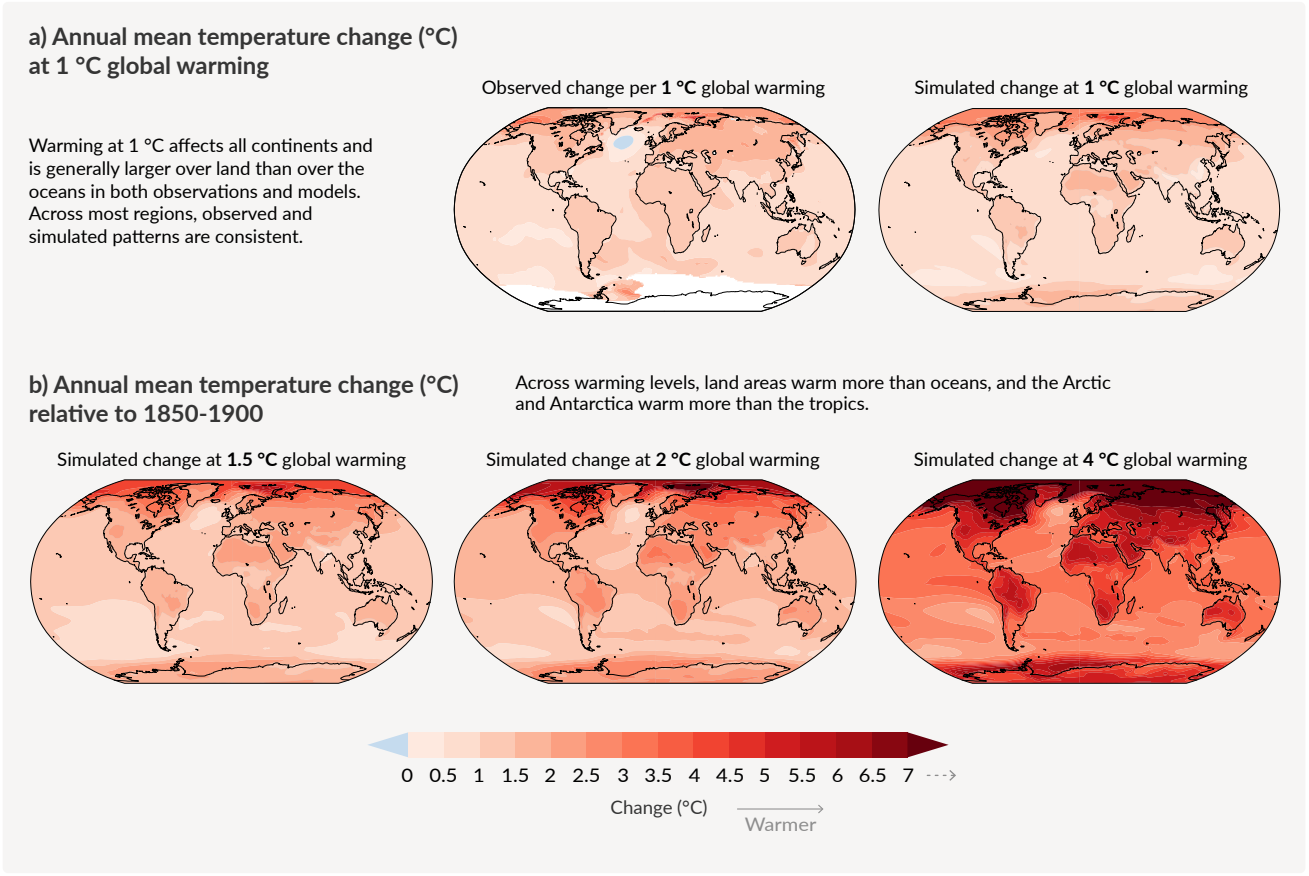
B.2.3 Some mid-latitude and semi-arid regions, and the South American Monsoon region, are projected to see the highest increase in the temperature of the hottest days, at about 1.5 to 2 times the rate of global warming (*high confidence*). The Arctic is projected to experience the highest increase in the temperature of the coldest days, at about 3 times the rate of global warming (*high confidence*). With additional global warming, the frequency of marine heatwaves will continue to increase (*high confidence*), particularly in the tropical ocean and the Arctic *(medium confidence).*
{Box 9.2, 11.1, 11.3, 11.9, Cross-Chapter Box 11.1, Cross-Chapter Box 12.1, 12.4, TS.2.4, TS.2.6} **(Figure SPM.6)**

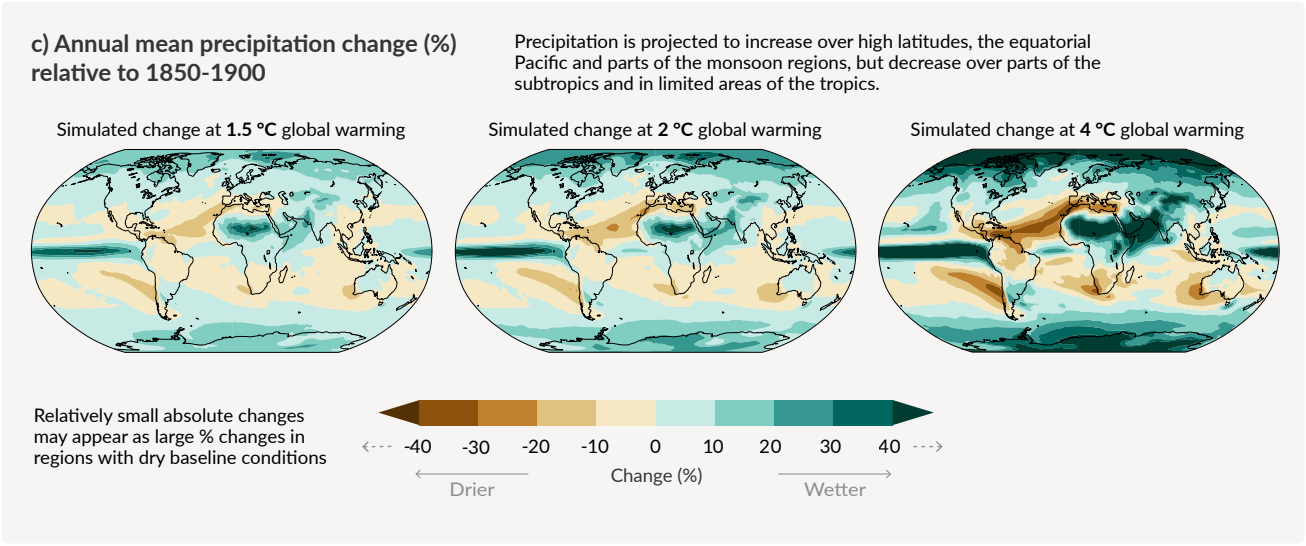
B.2.4 It is *very likely* that heavy precipitation events will intensify and become more frequent in most regions with additional global warming. At the global scale, extreme daily precipitation events are projected to intensify by about 7% for each 1°C of global warming (*high confidence*). The proportion of intense tropical cyclones (categories 4-5) and peak wind speeds of the most intense tropical cyclones are projected to increase at the global scale with increasing global warming (*high confidence*).
{8.2, 11.4, 11.7, 11.9, Cross-Chapter Box 11.1, Box TS.6, TS.4.3.1} **(Figure SPM.5, Figure SPM.6)**

B.2.5 Additional warming is projected to further amplify permafrost thawing, and loss of seasonal snow cover, of land ice and of Arctic sea ice (*high confidence*). The Arctic is *likely* to be practically sea ice free in September[31] at least once before 2050 under the five illustrative scenarios considered in this report, with more frequent occurrences for higher warming levels. There is *low confidence* in the projected decrease of Antarctic sea ice.
{4.3, 4.5, 7.4, 8.2, 8.4, Box 8.2, 9.3, 9.5, 12.4, Cross-Chapter Box 12.1, Atlas.5, Atlas.6, Atlas.8, Atlas.9, Atlas.11, TS.2.5} **(Figure SPM.8)**

[31] monthly average sea ice area of less than 1 million km^2 which is about 15% of the average September sea ice area observed in 1979-1988

With every increment of global warming, changes get larger in regional mean temperature, precipitation and soil moisture





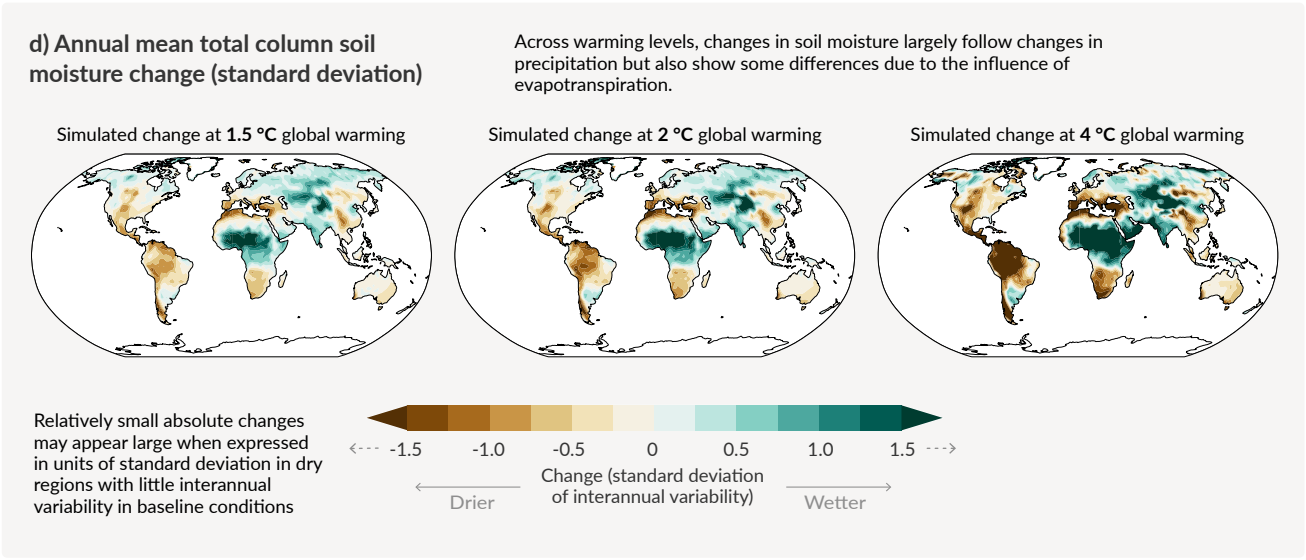


Figure SPM.5: Changes in annual mean surface temperature, precipitation, and soil moisture.

Panel a) Comparison of observed and simulated annual mean surface temperature change. The **left map** shows the observed changes in annual mean surface temperature in the period of 1850–2020 per °C of global warming (°C). The local (i.e., grid point) observed annual mean surface temperature changes are linearly regressed against the global surface temperature in the period 1850–2020. Observed temperature data are from Berkeley Earth, the dataset with the largest coverage and highest horizontal resolution. Linear regression is applied to all years for which data at the corresponding grid point is available. The regression method was used to take into account the complete observational time series and thereby reduce the role of internal variability at the grid point level. White indicates areas where time coverage was 100 years or less and thereby too short to calculate a reliable linear regression. The **right map** is based on model simulations and shows change in annual multi-model mean simulated temperatures at a global warming level of 1°C (20-year mean global surface temperature change relative to 1850–1900). The triangles at each end of the color bar indicate out-of-bound values, that is, values above or below the given limits.

Panel b) Simulated annual mean temperature change (°C), panel c) precipitation change (%), and panel d) total column soil moisture change (standard deviation of interannual variability) at global warming levels of 1.5°C, 2°C and 4°C (20-yr mean global surface temperature change relative to 1850–1900). Simulated changes correspond to CMIP6 multi-model mean change (median change for soil moisture) at the corresponding global warming level, i.e. the same method as for the right map in panel a).

In **panel c),** high positive percentage changes in dry regions may correspond to small absolute changes. In **panel d),** the unit is the standard deviation of interannual variability in soil moisture during 1850–1900. Standard deviation is a widely used metric in characterizing drought severity. A projected reduction in mean soil moisture by one standard deviation corresponds to soil moisture conditions typical of droughts that occurred about once every six years during 1850–1900. In panel d), large changes in dry regions with little interannual variability in the baseline conditions can correspond to small absolute change. The triangles at each end of the color bars indicate out-of-bound values, that is, values above or below the given limits. Results from all models reaching the corresponding warming level in any of the five illustrative scenarios (SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5) are averaged. Maps of annual mean temperature and precipitation changes at a global warming level of 3°C are available in Figure 4.31 and Figure 4.32 in Section 4.6.

Corresponding maps of panels b), c) and d) including hatching to indicate the level of model agreement at grid-cell level are found in Figures 4.31, 4.32 and 11.19, respectively; as highlighted in CC-box Atlas.1, grid-cell level hatching is not informative for larger spatial scales (e.g., over AR6 reference regions) where the aggregated signals are less affected by small-scale variability leading to an increase in robustness.

{TS.1.3.2, Figure TS.3, Figure TS.5, Figure 1.14, 4.6.1, Cross-Chapter Box 11.1, Cross-Chapter Box Atlas.1}

Projected changes in extremes are larger in frequency and intensity with every additional increment of global warming

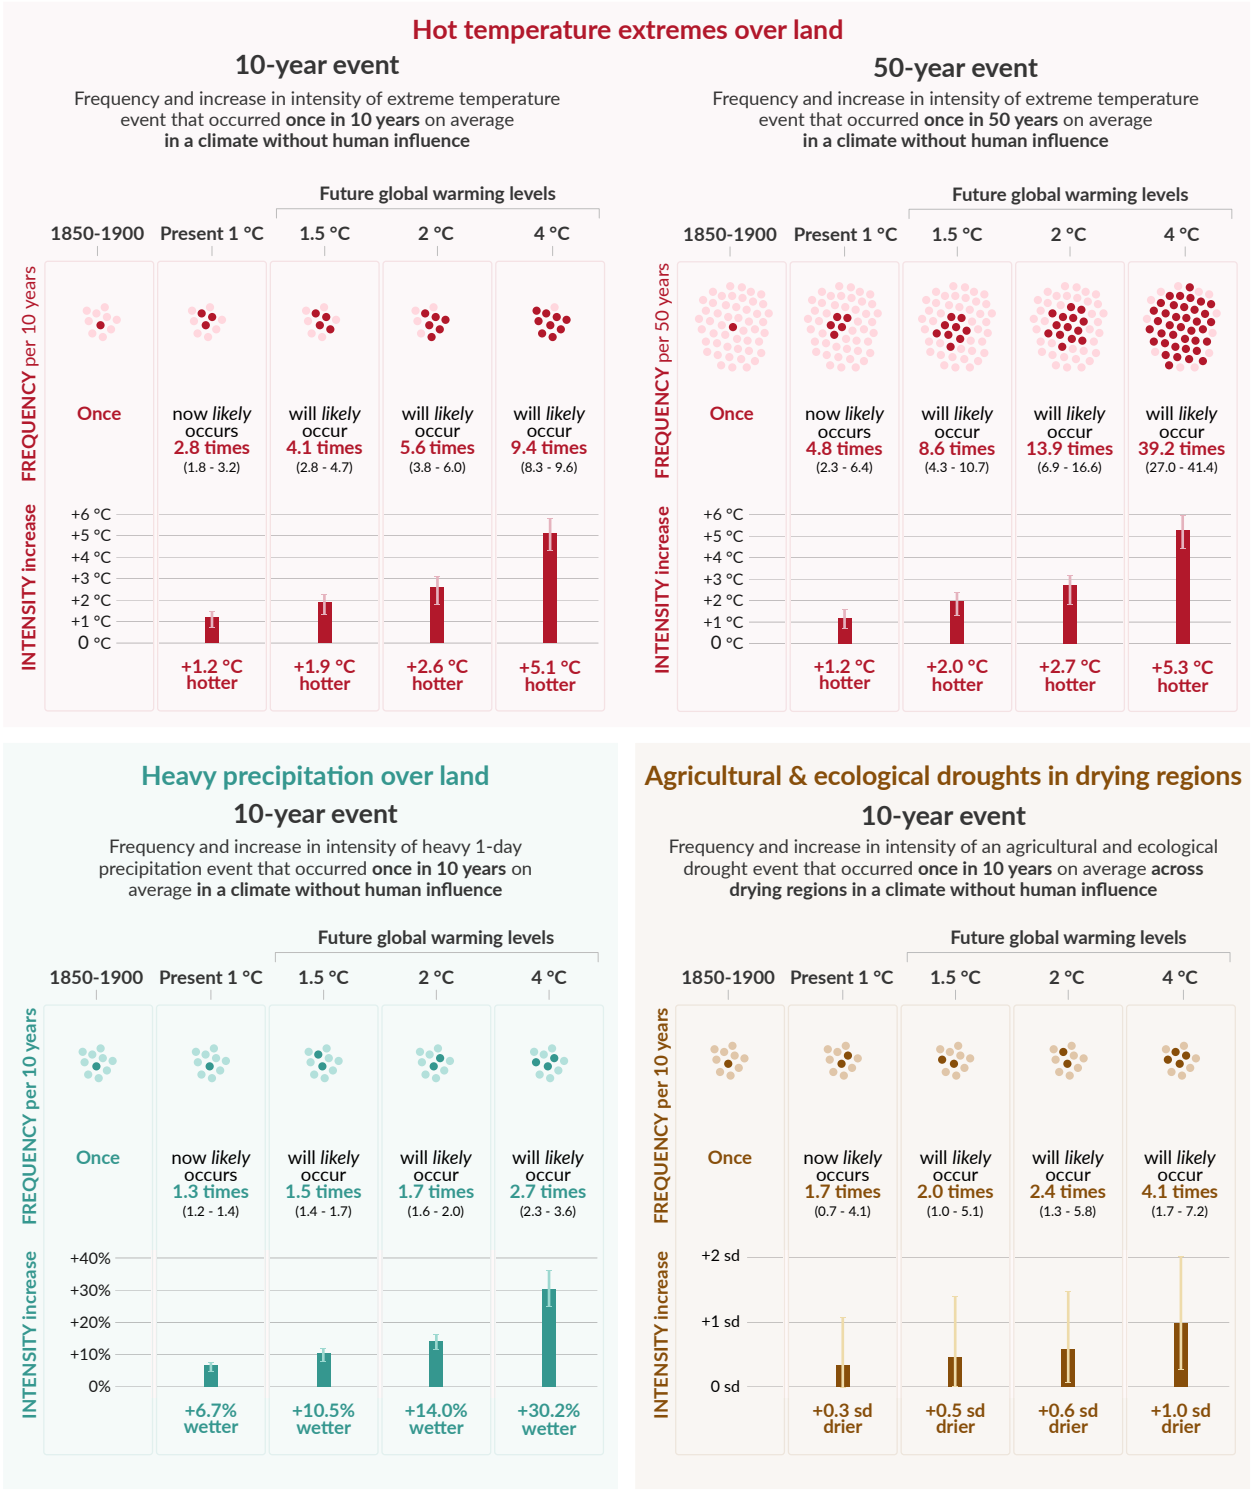

Figure SPM.6: Projected changes in the intensity and frequency of hot temperature extremes over land, extreme precipitation over land, and agricultural and ecological droughts in drying regions.

Projected changes are shown at global warming levels of 1°C, 1.5°C, 2°C, and 4°C and are relative to 1850-1900[9] representing a climate without human influence. The figure depicts frequencies and increases in intensity of 10- or 50-year extreme events from the base period (1850-1900) under different global warming levels.

Hot temperature extremes are defined as the daily maximum temperatures over land that were exceeded on average once in a decade (10-year event) or once in 50 years (50-year event) during the 1850–1900 reference period. **Extreme precipitation events** are defined as the daily precipitation amount over land that was exceeded on average once in a decade during the 1850–1900 reference period. **Agricultural and ecological drought events** are defined as the annual average of total column soil moisture below the 10th percentile of the 1850–1900 base period. These extremes are defined on model grid box scale. For hot temperature extremes and extreme precipitation, results are shown for the global land. For agricultural and ecological drought, results are shown for drying regions only, which correspond to the AR6 regions in which there is at least *medium confidence* in a projected increase in agricultural/ecological drought at the 2°C warming level compared to the 1850–1900 base period in CMIP6. These regions include W. North-America, C. North-America, N. Central-America, S. Central-America, Caribbean, N. South-America, N.E. South-America, South-American-Monsoon, S.W. South-America, S. South-America, West & Central-Europe, Mediterranean, W. Southern-Africa, E. Southern-Africa, Madagascar, E. Australia, S. Australia (Caribbean is not included in the calculation of the figure because of the too small number of full land grid cells). The non-drying regions do not show an overall increase or decrease in drought severity. Projections of changes in agricultural and ecological droughts in the CMIP5 multi-model ensemble differ from those in CMIP6 in some regions, including in part of Africa and Asia. Assessments on projected changes in meteorological and hydrological droughts are provided in Chapter 11. {11.6, 11.9}

In the **'frequency' section,** each year is represented by a dot. The dark dots indicate years in which the extreme threshold is exceeded, while light dots are years when the threshold is not exceeded. Values correspond to the medians (in bold) and their respective 5–95% range based on the multi-model ensemble from simulations of CMIP6 under different SSP scenarios. For consistency, the number of dark dots is based on the rounded-up median. In the **'intensity' section,** medians and their 5–95% range, also based on the multi-model ensemble from simulations of CMIP6, are displayed as dark and light bars, respectively. Changes in the intensity of hot temperature extremes and extreme precipitations are expressed as degree Celsius and percentage. As for agricultural and ecological drought, intensity changes are expressed as fractions of standard deviation of annual soil moisture.

{11.1, 11.3, 11.4, 11.6, Figure 11.12, Figure 11.15, Figure 11.6, Figure 11.7, Figure 11.18}

B.3 Continued global warming is projected to further intensify the global water cycle, including its variability, global monsoon precipitation and the severity of wet and dry events.

{4.3, 4.4, 4.5, 4.6, 8.2, 8.3, 8.4, 8.5, Box 8.2, 11.4, 11.6, 11.9, 12.4, Atlas.3} **(Figure SPM.5, Figure SPM.6)**

B.3.1 There is strengthened evidence since AR5 that the global water cycle will continue to intensify as global temperatures rise (*high confidence*), with precipitation and surface water flows projected to become more variable over most land regions within seasons (*high confidence*) and from year to year (*medium confidence*). The average annual global land precipitation is projected to increase by 0–5% under the very low GHG emissions scenario (SSP1-1.9), 1.5-8% for the intermediate GHG emissions scenario (SSP2-4.5) and 1–13% under the very high GHG emissions scenario (SSP5-8.5) by 2081–2100 relative to 1995-2014 (*likely* ranges). Precipitation is projected to increase over high latitudes, the equatorial Pacific and parts of the monsoon regions, but decrease over parts of the subtropics and limited areas in the tropics in SSP2-4.5, SSP3-7.0 and SSP5-8.5 (*very likely*). The portion of the global land experiencing detectable increases or decreases in seasonal mean precipitation is projected to increase (*medium confidence*). There is *high confidence* in an earlier onset of spring snowmelt, with higher peak flows at the expense of summer flows in snow-dominated regions globally.
{4.3, 4.5, 4.6, 8.2, 8.4, Atlas.3, TS.2.6, Box TS.6, TS.4.3} **(Figure SPM.5)**

B.3.2 A warmer climate will intensify very wet and very dry weather and climate events and seasons, with implications for flooding or drought (*high confidence*), but the location and frequency of these events depend on projected changes in regional atmospheric circulation, including monsoons and mid-latitude storm tracks. It is *very likely* that rainfall variability related to the El Niño–Southern Oscillation is projected to be amplified by the second half of the 21st century in the SSP2-4.5, SSP3-7.0 and SSP5-8.5 scenarios.
{4.3, 4.5, 4.6, 8.2, 8.4, 8.5, 11.4, 11.6, 11.9, 12.4, TS.2.6, TS.4.2, Box TS.6} **(Figure SPM.5, Figure SPM.6)**

B.3.3 Monsoon precipitation is projected to increase in the mid- to long term at global scale, particularly over South and Southeast Asia, East Asia and West Africa apart from the far west Sahel (*high confidence*). The monsoon season is projected to have a delayed onset over North and South America and West Africa (*high confidence*) and a delayed retreat over West Africa (*medium confidence*).
{4.4, 4.5, 8.2, 8.3, 8.4, Box 8.2, Box TS.13}

B.3.4 A projected southward shift and intensification of Southern Hemisphere summer mid-latitude storm tracks and associated precipitation is *likely* in the long term under high GHG emissions scenarios (SSP3-7.0, SSP5-8.5), but in the near term the effect of stratospheric ozone recovery counteracts these changes (*high confidence*). There is *medium confidence* in a continued poleward shift of storms and their precipitation in the North Pacific, while there is *low confidence* in projected changes in the North Atlantic storm tracks.
{TS.4.2, 4.4, 4.5, 8.4, TS.2.3}

B.4 Under scenarios with increasing CO_2 emissions, the ocean and land carbon sinks are projected to be less effective at slowing the accumulation of CO_2 in the atmosphere.

{4.3, 5.2, 5.4, 5.5, 5.6} **(Figure SPM.7)**

B.4.1 While natural land and ocean carbon sinks are projected to take up, in absolute terms, a progressively larger amount of CO_2 under higher compared to lower CO_2 emissions scenarios, they become less effective, that is, the proportion of emissions taken up by land and ocean decrease with increasing cumulative CO_2 emissions. This is projected to result in a higher proportion of emitted CO_2 remaining in the atmosphere (*high confidence*).
{5.2, 5.4, Box TS.5} **(Figure SPM.7)**

B.4.2 Based on model projections, under the intermediate scenario that stabilizes atmospheric CO_2 concentrations this century (SSP2-4.5), the rates of CO_2 taken up by the land and oceans are projected to decrease in the second half of the 21st century (*high confidence*). Under the very low and low GHG emissions scenarios (SSP1-1.9, SSP1-2.6), where CO_2 concentrations peak and decline during the 21st century, land and oceans begin to take up less carbon in response to declining atmospheric CO_2 concentrations (*high confidence*) and turn into a weak net source by 2100 under SSP1-1.9 (*medium confidence*). It is *very unlikely* that the combined global land and ocean sink will turn into a source by 2100 under scenarios without net negative emissions[32] (SSP2-4.5, SSP3-7.0, SSP5-8.5).
{4.3, 5.4, 5.5, 5.6, Box TS.5, TS.3.3}

B.4.3 The magnitude of feedbacks between climate change and the carbon cycle becomes larger but also more uncertain in high CO_2 emissions scenarios (*very high confidence*). However, climate model projections show that the uncertainties in atmospheric CO_2 concentrations by 2100 are dominated by the differences between emissions scenarios (*high confidence*). Additional ecosystem responses to warming not yet fully included in climate models, such as CO_2 and CH_4 fluxes from wetlands, permafrost thaw and wildfires, would further increase concentrations of these gases in the atmosphere (*high confidence*).
{5.4, Box TS.5, TS.3.2}

[32] These projected adjustments of carbon sinks to stabilization or decline of atmospheric CO_2 are accounted for in calculations of remaining carbon budgets.

The proportion of CO_2 emissions taken up by land and ocean carbon sinks is smaller in scenarios with higher cumulative CO_2 emissions

Total cumulative CO_2 emissions **taken up by land and oceans** (colours) and remaining in the atmosphere (grey) under the five illustrative scenarios from 1850 to 2100

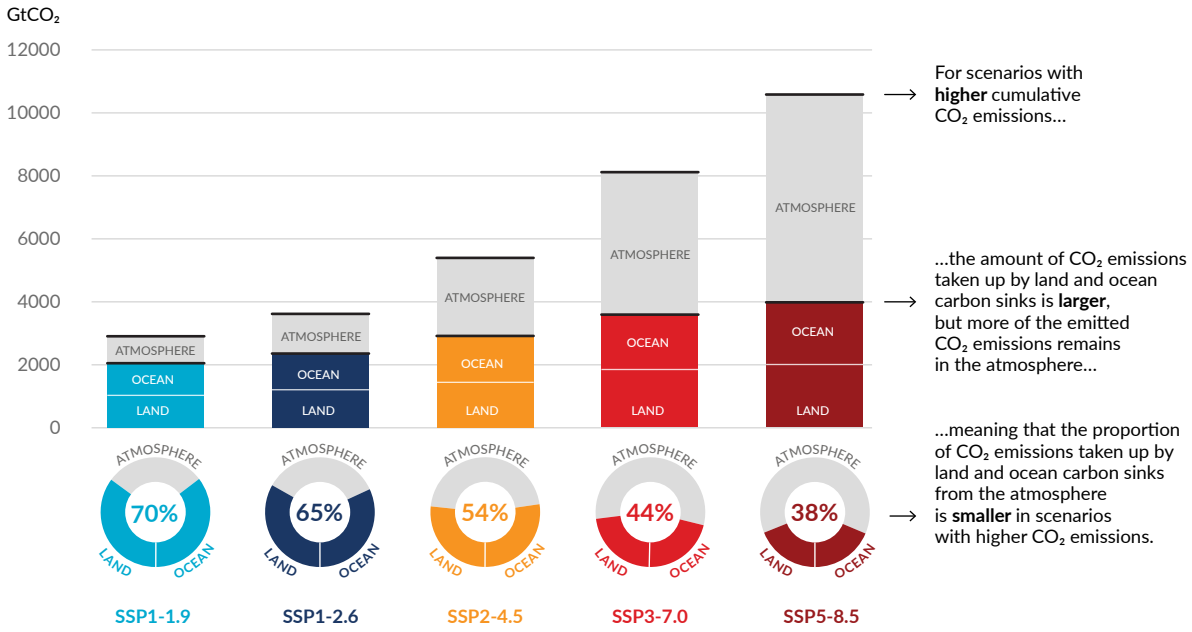

Figure SPM.7: Cumulative anthropogenic CO_2 emissions taken up by land and ocean sinks by 2100 under the five illustrative scenarios.

The cumulative anthropogenic (human-caused) carbon dioxide (CO_2) emissions taken up by the land and ocean sinks under the five illustrative scenarios (SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5) are simulated from 1850 to 2100 by CMIP6 climate models in the concentration-driven simulations. Land and ocean carbon sinks respond to past, current and future emissions, therefore cumulative sinks from 1850 to 2100 are presented here. During the historical period (1850-2019) the observed land and ocean sink took up 1430 $GtCO_2$ (59% of the emissions).

The **bar chart** illustrates the projected amount of cumulative anthropogenic CO_2 emissions ($GtCO_2$) between 1850 and 2100 remaining in the atmosphere (grey part) and taken up by the land and ocean (coloured part) in the year 2100. The **doughnut chart** illustrates the proportion of the cumulative anthropogenic CO_2 emissions taken up by the land and ocean sinks and remaining in the atmosphere in the year 2100. Values in % indicate the proportion of the cumulative anthropogenic CO_2 emissions taken up by the combined land and ocean sinks in the year 2100. The overall anthropogenic carbon emissions are calculated by adding the net global land use emissions from CMIP6 scenario database to the other sectoral emissions calculated from climate model runs with prescribed CO_2 concentrations[33]. Land and ocean CO_2 uptake since 1850 is calculated from the net biome productivity on land, corrected for CO_2 losses due to land-use change by adding the land-use change emissions, and net ocean CO_2 flux.

{Box TS.5, Box TS.5, Figure 1, 5.2.1, Table 5.1, 5.4.5, Figure 5.25}

[33] The other sectoral emissions are calculated as the residual of the net land and ocean CO_2 uptake and the prescribed atmospheric CO_2 concentration changes in the CMIP6 simulations. These calculated emissions are net emissions and do not separate gross anthropogenic emissions from removals, which are included implicitly.

B.5 Many changes due to past and future greenhouse gas emissions are irreversible for centuries to millennia, especially changes in the ocean, ice sheets and global sea level. {Cross-Chapter Box 2.4, 2.3, 4.3, 4.5, 4.7, 5.3, 9.2, 9.4, 9.5, 9.6, Box 9.4} **(Figure SPM.8)**

B.5.1 Past GHG emissions since 1750 have committed the global ocean to future warming (*high confidence*). Over the rest of the 21st century, *likely* ocean warming ranges from 2–4 (SSP1-2.6) to 4–8 times (SSP5-8.5) the 1971–2018 change. Based on multiple lines of evidence, upper ocean stratification (*virtually certain*), ocean acidification (*virtually certain*) and ocean deoxygenation (*high confidence*) will continue to increase in the 21st century, at rates dependent on future emissions. Changes are irreversible on centennial to millennial time scales in global ocean temperature (*very high confidence*), deep ocean acidification (*very high confidence*) and deoxygenation (*medium confidence*).
{4.3, 4.5, 4.7, 5.3, 9.2, TS.2.4} **(Figure SPM.8)**

B.5.2 Mountain and polar glaciers are committed to continue melting for decades or centuries (*very high confidence*). Loss of permafrost carbon following permafrost thaw is irreversible at centennial timescales (*high confidence*). Continued ice loss over the 21st century is *virtually certain* for the Greenland Ice Sheet and *likely* for the Antarctic Ice Sheet. There is *high confidence* that total ice loss from the Greenland Ice Sheet will increase with cumulative emissions. There is *limited evidence* for low-likelihood, high-impact outcomes (resulting from ice sheet instability processes characterized by deep uncertainty and in some cases involving tipping points) that would strongly increase ice loss from the Antarctic Ice Sheet for centuries under high GHG emissions scenarios[34]. {4.3, 4.7, 5.4, 9.4, 9.5, Box 9.4, Box TS.1, TS.2.5}

B.5.3 It is *virtually certain* that global mean sea level will continue to rise over the 21st century. Relative to 1995-2014, the *likely* global mean sea level rise by 2100 is 0.28-0.55 m under the very low GHG emissions scenario (SSP1-1.9), 0.32-0.62 m under the low GHG emissions scenario (SSP1-2.6), 0.44-0.76 m under the intermediate GHG emissions scenario (SSP2-4.5), and 0.63-1.01 m under the very high GHG emissions scenario (SSP5-8.5), and by 2150 is 0.37-0.86 m under the very low scenario (SSP1-1.9), 0.46-0.99 m under the low scenario (SSP1-2.6), 0.66-1.33 m under the intermediate scenario (SSP2-4.5), and 0.98-1.88 m under the very high scenario (SSP5-8.5) (*medium confidence*)[35]. Global mean sea level rise above the *likely* range – approaching 2 m by 2100 and 5 m by 2150 under a very high GHG emissions scenario (SSP5-8.5) (*low confidence*) – cannot be ruled out due to deep uncertainty in ice sheet processes.
{4.3, 9.6, Box 9.4, Box TS.4} **(Figure SPM.8)**

B.5.4 In the longer term, sea level is committed to rise for centuries to millennia due to continuing deep ocean warming and ice sheet melt, and will remain elevated for thousands of years (*high confidence*). Over the next 2000 years, global mean sea level will rise by about 2 to 3 m if warming is limited to 1.5°C, 2 to 6 m if limited to 2°C and 19 to 22 m with 5°C of warming, and it will continue to rise over subsequent millennia (*low confidence*). Projections of multi-millennial global mean sea level rise are consistent with reconstructed levels during past warm climate periods: *likely* 5–10 m higher than today around 125,000 years ago, when global temperatures were *very likely* 0.5°C–1.5°C higher than 1850–1900; and *very likely* 5–25 m higher roughly 3 million years ago, when global temperatures were 2.5°C–4°C higher (*medium confidence*).
{2.3, Cross-Chapter Box 2.4, 9.6, Box TS.2, Box TS.4, Box TS.9}

[34] Low-likelihood, high-impact outcomes are those whose probability of occurrence is low or not well known (as in the context of deep uncertainty) but whose potential impacts on society and ecosystems could be high. A tipping point is a critical threshold beyond which a system reorganizes, often abruptly and/or irreversibly. {Cross-Chapter Box 1.3, 1.4, 4.7}

[35] To compare to the 1986–2005 baseline period used in AR5 and SROCC, add 0.03 m to the global mean sea level rise estimates. To compare to the 1900 baseline period used in Figure SPM.8, add 0.16 m.

Human activities affect all the major climate system components, with some responding over decades and others over centuries

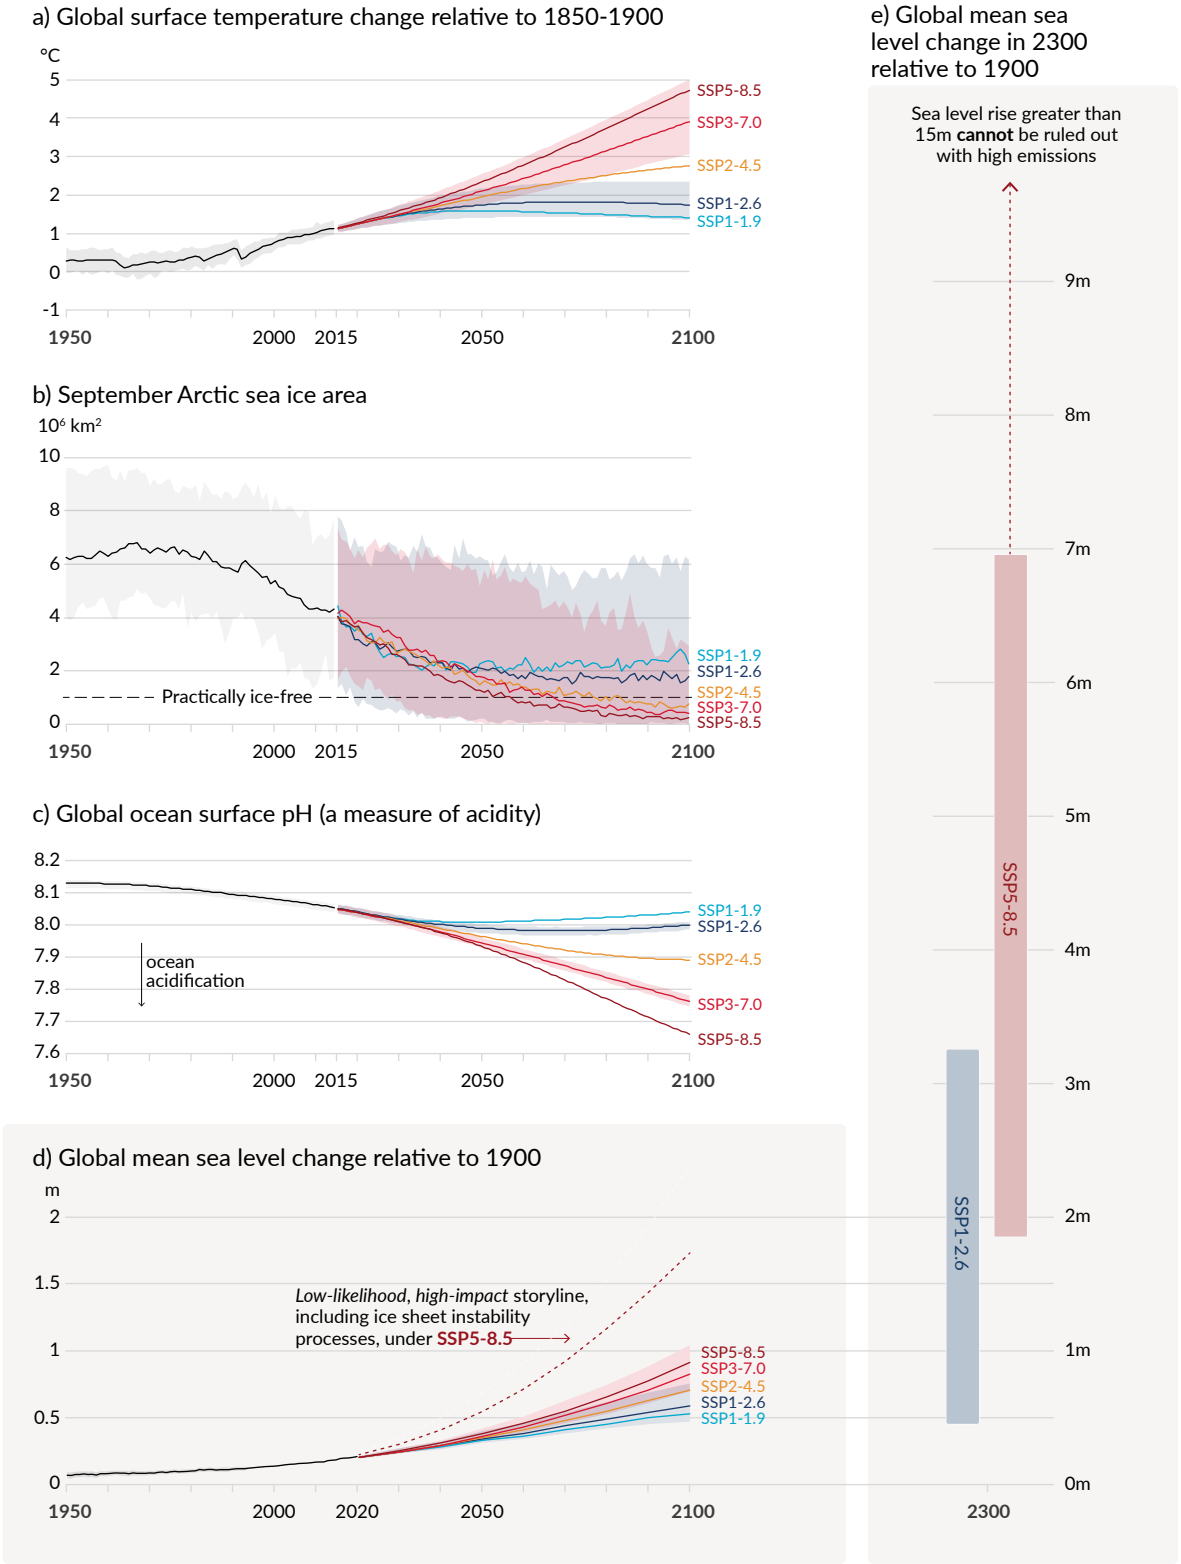

Figure SPM.8: Selected indicators of global climate change under the five illustrative scenarios used in this report.

The projections for each of the five scenarios are shown in colour. Shades represent uncertainty ranges – more detail is provided for each panel below. The black curves represent the historical simulations (panels a, b, c) or the observations (panel d). Historical values are included in all graphs to provide context for the projected future changes.

Panel a) Global surface temperature changes in °C relative to 1850–1900. These changes were obtained by combining CMIP6 model simulations with observational constraints based on past simulated warming, as well as an updated assessment of equilibrium climate sensitivity (see Box SPM.1). Changes relative to 1850–1900 based on 20-year averaging periods are calculated by adding 0.85°C (the observed global surface temperature increase from 1850–1900 to 1995–2014) to simulated changes relative to 1995–2014. *Very likely* ranges are shown for SSP1-2.6 and SSP3-7.0.

Panel b) September Arctic sea ice area in 10^6 km^2 based on CMIP6 model simulations. *Very likely* ranges are shown for SSP1-2.6 and SSP3-7.0. The Arctic is projected to be practically ice-free near mid-century under mid- and high GHG emissions scenarios.

Panel c) Global ocean surface pH (a measure of acidity) based on CMIP6 model simulations. *Very likely* ranges are shown for SSP1-2.6 and SSP3-7.0.

Panel d) Global mean sea level change in meters relative to 1900. The historical changes are observed (from tide gauges before 1992 and altimeters afterwards), and the future changes are assessed consistently with observational constraints based on emulation of CMIP, ice sheet, and glacier models. *Likely* ranges are shown for SSP1-2.6 and SSP3-7.0. Only *likely* ranges are assessed for sea level changes due to difficulties in estimating the distribution of deeply uncertain processes. The dashed curve indicates the potential impact of these deeply uncertain processes. It shows the 83rd percentile of SSP5-8.5 projections that include low-likelihood, high-impact ice sheet processes that cannot be ruled out; because of *low confidence* in projections of these processes, this curve does not constitute part of a *likely* range. Changes relative to 1900 are calculated by adding 0.158 m (observed global mean sea level rise from 1900 to 1995–2014) to simulated and observed changes relative to 1995–2014.

Panel e): Global mean sea level change at 2300 in meters relative to 1900. Only SSP1-2.6 and SSP5-8.5 are projected at 2300, as simulations that extend beyond 2100 for the other scenarios are too few for robust results. The 17th–83rd percentile ranges are shaded. The dashed arrow illustrates the 83rd percentile of SSP5-8.5 projections that include low-likelihood, high-impact ice sheet processes that cannot be ruled out.

Panels b) and c) are based on single simulations from each model, and so include a component of internal variability. Panels a), d) and e) are based on long-term averages, and hence the contributions from internal variability are small.

{Figure TS.8, Figure TS.11, Box TS.4 Figure 1, Box TS.4 Figure 1, 4.3, 9.6, Figure 4.2, Figure 4.8, Figure 4.11, Figure 9.27}

C. Climate Information for Risk Assessment and Regional Adaptation

Physical climate information addresses how the climate system responds to the interplay between human influence, natural drivers and internal variability. Knowledge of the climate response and the range of possible outcomes, including low-likelihood, high impact outcomes, informs climate services – the assessment of climate-related risks and adaptation planning. Physical climate information at global, regional and local scales is developed from multiple lines of evidence, including observational products, climate model outputs and tailored diagnostics.

C.1 Natural drivers and internal variability will modulate human-caused changes, especially at regional scales and in the near term, with little effect on centennial global warming. These modulations are important to consider in planning for the full range of possible changes.

{1.4, 2.2, 3.3, Cross-Chapter Box 3.1, 4.4, 4.6, Cross-Chapter Box 4.1, 4.4, Box 7.2, 8.3, 8.5, 9.2, 10.3, 10.4, 10.6, 11.3, 12.5, Atlas.4, Atlas.5, Atlas.8, Atlas.9, Atlas.10, Cross-Chapter Box Atlas.2, Atlas.11}

C.1.1 The historical global surface temperature record highlights that decadal variability has enhanced and masked underlying human-caused long-term changes, and this variability will continue into the future (*very high confidence*). For example, internal decadal variability and variations in solar and volcanic drivers partially masked human-caused surface global warming during 1998–2012, with pronounced regional and seasonal signatures (*high confidence*). Nonetheless, the heating of the climate system continued during this period, as reflected in both the continued warming of the global ocean (*very high confidence*) and in the continued rise of hot extremes over land (*medium confidence*).
{1.4, 3.3, Cross-Chapter Box 3.1, 4.4, Box 7.2, 9.2, 11.3, Cross-Section Box TS.1} **(Figure SPM.1)**

C.1.2 Projected human caused changes in mean climate and climatic impact-drivers (CIDs)[36], including extremes, will be either amplified or attenuated by internal variability[37] (*high confidence*). Near-term cooling at any particular location with respect to present climate could occur and would be consistent with the global surface temperature increase due to human influence (*high confidence*).
{1.4, 4.4, 4.6, 10.4, 11.3, 12.5, Atlas.5, Atlas.10, Atlas.11, TS.4.2}

C.1.3 Internal variability has largely been responsible for the amplification and attenuation of the observed human-caused decadal-to-multi-decadal mean precipitation changes in many land regions *(high confidence)*. At global and regional scales, near-term changes in monsoons will be dominated by the effects of internal variability (*medium confidence*). In addition to internal variability influence, near-term projected changes in precipitation at global and regional scales are uncertain because of model uncertainty and uncertainty in forcings from natural and anthropogenic aerosols (*medium confidence*).
{1.4, 4.4, 8.3, 8.5, 10.3, 10.4, 10.5, 10.6, Atlas.4, Atlas.8, Atlas.9, Atlas.10, Cross-Chapter Box Atlas.2, Atlas.11, TS.4.2, Box TS.6, Box TS.13}

[36] Climatic impact-drivers (CIDs) are physical climate system conditions (e.g., means, events, extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions. CID types include heat and cold, wet and dry, wind, snow and ice, coastal and open ocean.

[37] The main internal variability phenomena include El Niño–Southern Oscillation, Pacific Decadal variability and Atlantic Multi-decadal variability through their regional influence.

C.1.4 Based on paleoclimate and historical evidence, it is *likely* that at least one large explosive volcanic eruption would occur during the 21st century[38]. Such an eruption would reduce global surface temperature and precipitation, especially over land, for one to three years, alter the global monsoon circulation, modify extreme precipitation and change many CIDs (*medium confidence*). If such an eruption occurs, this would therefore temporarily and partially mask human-caused climate change.
{4.4, Cross-Chapter Box 4.1, 2.2, 8.5, TS.2.1}

C.2 With further global warming, every region is projected to increasingly experience concurrent and multiple changes in climatic impact-drivers. Changes in several climatic impact-drivers would be more widespread at 2°C compared to 1.5°C global warming and even more widespread and/or pronounced for higher warming levels.

{8.2, 9.3, 9.5, 9.6, Box 10.3, Box 11.3, Box 11.4, 11.3, 11.4, 11.5, 11.6, 11.7, 11.9, 12.2, 12.3, 12.4, 12.5, Atlas.4, Atlas.5, Atlas.6, Atlas.7, Atlas.8, Atlas.9, Atlas.10, Atlas.11, Cross-Chapter Box 11.1, Cross-Chapter Box 12.1} **(Table SPM.1, Figure SPM.9)**

C.2.1 All regions[39] are projected to experience further increases in hot climatic impact-drivers (CIDs) and decreases in cold CIDs (*high confidence*). Further decreases are projected in permafrost, snow, glaciers and ice sheets, lake and Arctic sea ice (*medium* to *high confidence*)[40]. These changes would be larger at 2°C global warming or above than at 1.5°C (*high confidence*). For example, extreme heat thresholds relevant to agriculture and health are projected to be exceeded more frequently at higher global warming levels (*high confidence*).
{9.3, 9.5, 11.3, 11.9, 12.3, 12.4, 12.5, Atlas.4, Atlas.5, Atlas.6, Atlas.7, Atlas.8, Atlas.9, Atlas.10, Atlas.11, TS.4.3, Cross-Chapter Box 11.1, Cross-Chapter Box 12.1} **(Table SPM.1, Figure SPM.9)**

C.2.2 At 1.5°C global warming, heavy precipitation and associated flooding are projected to intensify and be more frequent in most regions in Africa and Asia (*high confidence*), North America (*medium* to *high confidence*)[40] and Europe (*medium confidence*). Also**,** more frequent and/or severe agricultural and ecological droughts are projected in a few regions in all continents except Asia compared to 1850–1900 (*medium confidence*); increases in meteorological droughts are also projected in a few regions (*medium confidence*). A small number of regions are projected to experience increases or decreases in mean precipitation (*medium confidence*).
{11.4, 11.5, 11.6, 11.9, Atlas.4, Atlas.5, Atlas.7, Atlas.8, Atlas.9, Atlas.10, Atlas.11, TS.4.3} **(Table SPM.1)**

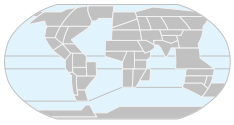
[38] Based on 2,500 year reconstructions, eruptions more negative than –1 W m^{-2} occur on average twice per century.

[39] Regions here refer to the AR6 WGI reference regions used in this Report to summarize information in sub-continental and oceanic regions. Changes are compared to averages over the last 20–40 years unless otherwise specified. {1.4, 12.4, Atlas.1, Interactive Atlas}.

[40] The specific level of confidence or likelihood depends on the region considered. Details can be found in the Technical Summary and the underlying Report.

C.2.3 At 2°C global warming and above, the level of confidence in and the magnitude of the change in droughts and heavy and mean precipitation increase compared to those at 1.5°C. Heavy precipitation and associated flooding events are projected to become more intense and frequent in the Pacific Islands and across many regions of North America and Europe (*medium* to *high confidence*)[40]. These changes are also seen in some regions in Australasia and Central and South America (*medium confidence*). Several regions in Africa, South America and Europe are projected to experience an increase in frequency and/or severity of agricultural and ecological droughts with *medium* to *high confidence*[40]; increases are also projected in Australasia, Central and North America, and the Caribbean with *medium confidence*. A small number of regions in Africa, Australasia, Europe and North America are also projected to be affected by increases in hydrological droughts, and several regions are projected to be affected by increases or decreases in meteorological droughts with more regions displaying an increase (*medium confidence*). Mean precipitation is projected to increase in all polar, northern European and northern North American regions, most Asian regions and two regions of South America (*high confidence*).
{11.4, 11.6, 11.9, 12.4, 12.5, Atlas.5, Atlas.7, Atlas.8, Atlas.9, Atlas.11, TS.4.3, Cross-Chapter Box 11.1, Cross-Chapter Box 12.1} **(Table SPM.1, Figure SPM.5, Figure SPM.6, Figure SPM.9)**

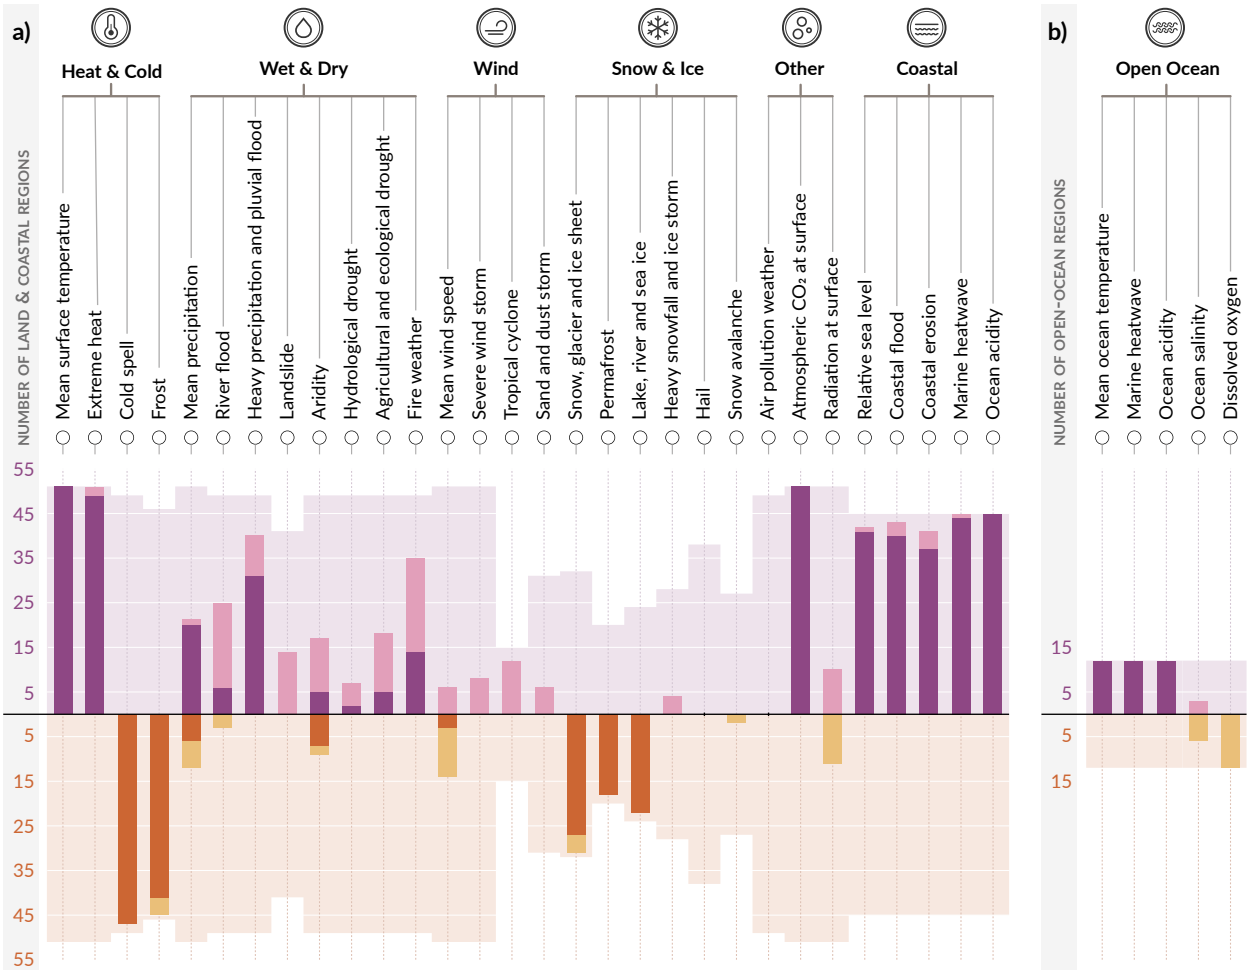
C.2.4 More CIDs across more regions are projected to change at 2°C and above compared to 1.5°C global warming (*high confidence*). Region-specific changes include intensification of tropical cyclones and/or extratropical storms (*medium confidence*), increases in river floods (*medium* to *high confidence*)[40], reductions in mean precipitation and increases in aridity (*medium* to *high confidence*)[40], and increases in fire weather (*medium* to *high confidence*)[40]. There is *low confidence* in most regions in potential future changes in other CIDs, such as hail, ice storms, severe storms, dust storms, heavy snowfall, and landslides.
{11.7, 11.9, 12.4, 12.5, Atlas.4, Atlas.6, Atlas.7, Atlas.8, Atlas.10, TS.4.3.1, TS.4.3.2, TS.5, Cross-Chapter Box, 11.1, Cross-Chapter Box 12.1} **(Table SPM.1, Figure SPM.9)**



C.2.5 It is *very likely* to *virtually certain*[40] that regional mean relative sea level rise will continue throughout the 21st century, except in a few regions with substantial geologic land uplift rates. Approximately two-thirds of the global coastline has a projected regional relative sea level rise within ±20% of the global mean increase (*medium confidence*). Due to relative sea level rise, extreme sea level events that occurred once per century in the recent past are projected to occur at least annually at more than half of all tide gauge locations by 2100 (*high confidence*). Relative sea level rise contributes to increases in the frequency and severity of coastal flooding in low-lying areas and to coastal erosion along most sandy coasts (*high confidence*).
{9.6, 12.4, 12.5, Box TS.4, TS.4.3, Cross-Chapter Box 12.1} **(Figure SPM.9)**

C.2.6 Cities intensify human-induced warming locally, and further urbanization together with more frequent hot extremes will increase the severity of heatwaves (*very high confidence*). Urbanization also increases mean and heavy precipitation over and/or downwind of cities (*medium confidence*) and resulting runoff intensity (*high confidence*). In coastal cities, the combination of more frequent extreme sea level events (due to sea level rise and storm surge) and extreme rainfall/riverflow events will make flooding more probable (*high confidence*).
{8.2, Box 10.3, 11.3, 12.4, Box TS.14}

C.2.7 Many regions are projected to experience an increase in the probability of compound events with higher global warming (*high confidence*). In particular, concurrent heatwaves and droughts are *likely* to become more frequent. Concurrent extremes at multiple locations become more frequent, including in crop-producing areas, at 2°C and above compared to 1.5°C global warming (*high confidence*).
{11.8, Box 11.3, Box 11.4, 12.3, 12.4, TS.4.3, Cross-Chapter Box 12.1} **(Table SPM.1)**



Multiple climatic impact-drivers are projected to change in all regions of the world

Climatic impact-drivers (CIDs) are physical climate system conditions (e.g., means, events, extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions. The CIDs are grouped into seven types, which are summarized under the icons in the figure. All regions are projected to experience changes in at least 5 CIDs. Almost all (96%) are projected to experience changes in at least 10 CIDs and half in at least 15 CIDs. For many CIDs there is wide geographical variation in where they change and so each region are projected to experience a specific set of CID changes. Each bar in the chart represents a specific geographical set of changes that can be explored in the WGI Interactive Atlas.

interactive-atlas.ipcc.ch

Number of land & coastal regions (a) and **open-ocean regions** (b) where each **climatic impact-driver** (CID) is projected to **increase** or **decrease** with ***high*** *confidence* (dark shade) or ***medium*** *confidence* (light shade)

BAR CHART LEGEND

- Regions with ***high*** *confidence* **increase**
- Regions with ***medium*** *confidence* **increase**
- Regions with ***high*** *confidence* **decrease**
- Regions with ***medium*** *confidence* **decrease**

LIGHTER-SHADED 'ENVELOPE' LEGEND

The height of the lighter shaded 'envelope' behind each bar represents the maximum number of regions for which each CID is relevant. The envelope is symmetrical about the x-axis showing the maximum possible number of relevant regions for CID increase (upper part) or decrease (lower part).

ASSESSED FUTURE CHANGES

Changes refer to a 20–30 year period centred around 2050 and/or consistent with 2°C global warming compared to a similar period within 1960-2014 or 1850-1900.

Figure SPM.9: Synthesis of the number of AR6 WGI reference regions where climatic impact-drivers are projected to change.

A total of 35 climatic impact-drivers (CIDs) grouped into seven types are shown: heat and cold, wet and dry, wind, snow and ice, coastal, open ocean and other. For each CID, the bar in the graph below displays the number of AR6 WGI reference regions where it is projected to change. The **colours** represent the direction of change and the level of confidence in the change: purple indicates an increase while brown indicates a decrease; darker and lighter shades refer to *high* and *medium confidence*, respectively. Lighter background colours represent the maximum number of regions for which each CID is broadly relevant.

Panel a) shows the 30 CIDs relevant to the **land and coastal regions** while **panel b)** shows the 5 CIDs relevant to the **open ocean regions.** Marine heatwaves and ocean acidity are assessed for coastal ocean regions in panel a) and for open ocean regions in panel b). Changes refer to a 20–30 year period centred around 2050 and/or consistent with 2°C global warming compared to a similar period within 1960-2014, except for hydrological drought and agricultural and ecological drought which is compared to 1850-1900. Definitions of the regions are provided in Atlas.1 and the Interactive Atlas (see *interactive-atlas.ipcc.ch*).

{Table TS.5, Figure TS.22, Figure TS.25, 11.9, 12.2, 12.4, Atlas.1} **(Table SPM.1)**

C.3 Low-likelihood outcomes, such as ice sheet collapse, abrupt ocean circulation changes, some compound extreme events and warming substantially larger than the assessed *very likely* range of future warming cannot be ruled out and are part of risk assessment.

{1.4, Cross-Chapter Box 1.3, Cross-Chapter Box 4.1, 4.3, 4.4, 4.8, 8.6, 9.2, Box 9.4, Box 11.2, 11.8, Cross-Chapter Box 12.1} **(Table SPM.1)**

C.3.1 If global warming exceeds the assessed *very likely* range for a given GHG emissions scenario, including low GHG emissions scenarios, global and regional changes in many aspects of the climate system, such as regional precipitation and other CIDs, would also exceed their assessed *very likely* ranges (*high confidence*). Such low-likelihood high-warming outcomes are associated with potentially very large impacts, such as through more intense and more frequent heatwaves and heavy precipitation, and high risks for human and ecological systems particularly for high GHG emissions scenarios.
{Cross-Chapter Box 1.3, 4.3, 4.4, 4.8, Box 9.4, Box 11.2, Cross-Chapter Box 12.1, TS.1.4, Box TS.3, Box TS.4} **(Table SPM.1)**

C.3.2 Low-likelihood, high-impact outcomes[34] could occur at global and regional scales even for global warming within the *very likely* range for a given GHG emissions scenario. The probability of low-likelihood, high impact outcomes increases with higher global warming levels (*high confidence*). Abrupt responses and tipping points of the climate system, such as strongly increased Antarctic ice sheet melt and forest dieback, cannot be ruled out (*high confidence*).
{1.4, 4.3, 4.4, 4.8, 5.4, 8.6, Box 9.4, Cross-Chapter Box 12.1, TS.1.4, TS.2.5, Box TS.3, Box TS.4, Box TS.9**} (Table SPM.1)**

C.3.3 If global warming increases, some compound extreme events[18] with low likelihood in past and current climate will become more frequent, and there will be a higher likelihood that events with increased intensities, durations and/or spatial extents unprecedented in the observational record will occur (*high confidence*).
{11.8, Box 11.2, Cross-Chapter Box 12.1, Box TS.3, Box TS.9}

C.3.4 The Atlantic Meridional Overturning Circulation is *very likely* to weaken over the 21st century for all emission scenarios. While there is *high confidence* in the 21st century decline, there is only *low confidence* in the magnitude of the trend. There is *medium confidence* that there will not be an abrupt collapse before 2100. If such a collapse were to occur, it would *very likely* cause abrupt shifts in regional weather patterns and water cycle, such as a southward shift in the tropical rain belt, weakening of the African and Asian monsoons and strengthening of Southern Hemisphere monsoons, and drying in Europe. {4.3, 8.6, 9.2, TS2.4, Box TS.3}

C.3.5 Unpredictable and rare natural events not related to human influence on climate may lead to low-likelihood, high impact outcomes. For example, a sequence of large explosive volcanic eruptions within decades has occurred in the past, causing substantial global and regional climate perturbations over several decades. Such events cannot be ruled out in the future, but due to their inherent unpredictability they are not included in the illustrative set of scenarios referred to in this Report. {2.2, Cross-Chapter Box 4.1, Box TS.3} **(Box SPM.1)**

D. Limiting Future Climate Change

Since AR5, estimates of remaining carbon budgets have been improved by a new methodology first presented in SR1.5, updated evidence, and the integration of results from multiple lines of evidence. A comprehensive range of possible future air pollution controls in scenarios is used to consistently assess the effects of various assumptions on projections of climate and air pollution. A novel development is the ability to ascertain when climate responses to emissions reductions would become discernible above natural climate variability, including internal variability and responses to natural drivers.

D.1 From a physical science perspective, limiting human-induced global warming to a specific level requires limiting cumulative CO_2 emissions, reaching at least net zero CO_2 emissions, along with strong reductions in other greenhouse gas emissions. Strong, rapid and sustained reductions in CH_4 emissions would also limit the warming effect resulting from declining aerosol pollution and would improve air quality.

{3.3, 4.6, 5.1, 5.2, 5.4, 5.5, 5.6, Box 5.2, Cross-Chapter Box 5.1, 6.7, 7.6, 9.6} **(Figure SPM.10, Table SPM.2)**

D.1.1 This Report reaffirms with *high confidence* the AR5 finding that there is a near-linear relationship between cumulative anthropogenic CO_2 emissions and the global warming they cause. Each 1000 $GtCO_2$ of cumulative CO_2 emissions is assessed to *likely* cause a 0.27°C to 0.63°C increase in global surface temperature with a best estimate of 0.45°C[41]. This is a narrower range compared to AR5 and SR1.5. This quantity is referred to as the transient climate response to cumulative CO_2 emissions (TCRE). This relationship implies that reaching net zero[42] anthropogenic CO_2 emissions is a requirement to stabilize human-induced global temperature increase at any level, but that limiting global temperature increase to a specific level would imply limiting cumulative CO_2 emissions to within a carbon budget[43]. {5.4, 5.5, TS.1.3, TS.3.3, Box TS.5} **(Figure SPM.10)**

[41] In the literature, units of °C per 1000 PgC are used, and the AR6 reports the TCRE *likely* range as 1.0°C to 2.3°C per 1000 PgC in the underlying report, with a best estimate of 1.65°C.

[42] condition in which anthropogenic carbon dioxide (CO_2) emissions are balanced by anthropogenic CO_2 removals over a specified period.

[43] The term carbon budget refers to the maximum amount of cumulative net global anthropogenic CO_2 emissions that would result in limiting global warming to a given level with a given probability, taking into account the effect of other anthropogenic climate forcers. This is referred to as the total carbon budget when expressed starting from the pre-industrial period, and as the remaining carbon budget when expressed from a recent specified date (see Glossary). Historical cumulative CO_2 emissions determine to a large degree warming to date, while future emissions cause future additional warming. The remaining carbon budget indicates how much CO_2 could still be emitted while keeping warming below a specific temperature level.

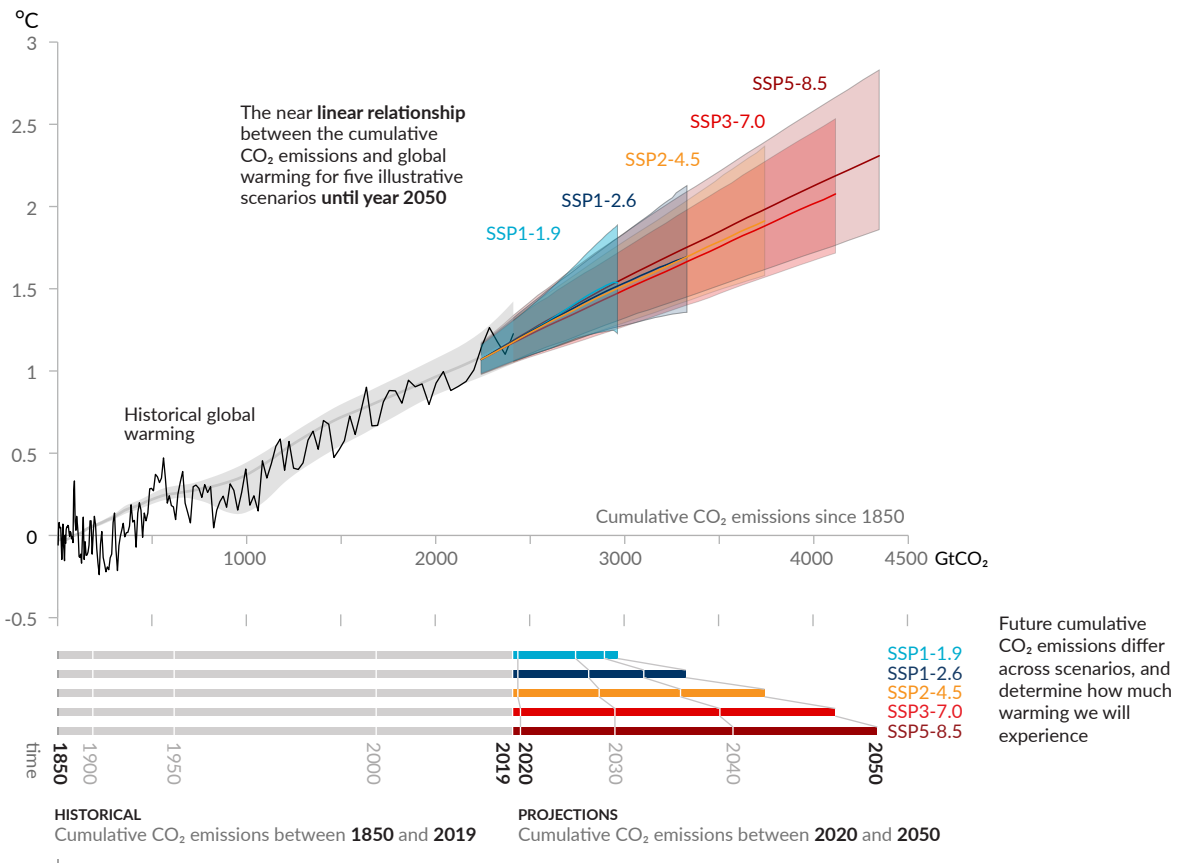


Figure SPM.10: Near-linear relationship between cumulative CO2 emissions and the increase in global surface temperature.

Top panel: Historical data (thin black line) shows observed global surface temperature increase in °C since 1850–1900 as a function of historical cumulative carbon dioxide (CO_2) emissions in $GtCO_2$ from 1850 to 2019. The grey range with its central line shows a corresponding estimate of the historical human-caused surface warming (see Figure SPM.2). Coloured areas show the assessed *very likely* range of global surface temperature projections, and thick coloured central lines show the median estimate as a function of cumulative CO_2 emissions from 2020 until year 2050 for the set of illustrative scenarios (SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5, see Figure SPM.4). Projections use the cumulative CO_2 emissions of each respective scenario, and the projected global warming includes the contribution from all anthropogenic forcers. The relationship is illustrated over the domain of cumulative CO_2 emissions for which there is *high confidence* that the transient climate response to cumulative CO_2 emissions (TCRE) remains constant, and for the time period from 1850 to 2050 over which global CO_2 emissions remain net positive under all illustrative scenarios as there is *limited evidence* supporting the quantitative application of TCRE to estimate temperature evolution under net negative CO_2 emissions.

Bottom panel: Historical and projected cumulative CO_2 emissions in $GtCO_2$ for the respective scenarios.

{Figure TS.18, Figure 5.31, Section 5.5}

D.1.2 Over the period 1850–2019, a total of 2390 ± 240 (*likely* range) $GtCO_2$ of anthropogenic CO_2 was emitted. Remaining carbon budgets have been estimated for several global temperature limits and various levels of probability, based on the estimated value of TCRE and its uncertainty, estimates of historical warming, variations in projected warming from non-CO_2 emissions, climate system feedbacks such as emissions from thawing permafrost, and the global surface temperature change after global anthropogenic CO_2 emissions reach net zero.
{5.1, 5.5, Box 5.2, TS.3.3} **(Table SPM.2)**

Table SPM.2: Estimates of historical CO_2 emissions and remaining carbon budgets. Estimated remaining carbon budgets are calculated from the beginning of 2020 and extend until global net zero CO_2 emissions are reached. They refer to CO_2 emissions, while accounting for the global warming effect of non-CO_2 emissions. Global warming in this table refers to human-induced global surface temperature increase, which excludes the impact of natural variability on global temperatures in individual years. {Table TS.3, Table 3.1, Table 5.1, Table 5.7, Table 5.8, 5.5.1, 5.5.2, Box 5.2}

Global warming between 1850–1900 and 2010–2019 *(°C)*	Historical cumulative CO_2 emissions from 1850 to 2019 *($GtCO_2$)*
1.07 (0.8–1.3; *likely* range)	2390 (± 240; *likely* range)

Approximate global warming relative to 1850–1900 until temperature limit *(°C)**(1)	Additional global warming relative to 2010–2019 until temperature limit *(°C)*	Estimated remaining carbon budgets from the beginning of 2020 *($GtCO_2$)* — *Likelihood of limiting global warming to temperature limit*(2)*					Variations in reductions in non-CO_2 emissions*(3)
		17%	*33%*	*50%*	*67%*	*83%*	
1.5	0.43	900	650	500	400	300	Higher or lower reductions in accompanying non-CO_2 emissions can increase or decrease the values on the left by 220 $GtCO_2$ or more
1.7	0.63	1450	1050	850	700	550	
2.0	0.93	2300	1700	1350	1150	900	

*(1) Values at each 0.1°C increment of warming are available in Tables TS.3 and 5.8.
*(2) This likelihood is based on the uncertainty in transient climate response to cumulative CO_2 emissions (TCRE) and additional Earth system feedbacks, and provides the probability that global warming will not exceed the temperature levels provided in the two left columns. Uncertainties related to historical warming (±550 $GtCO_2$) and non-CO_2 forcing and response (±220 $GtCO_2$) are partially addressed by the assessed uncertainty in TCRE, but uncertainties in recent emissions since 2015 (±20 $GtCO_2$) and the climate response after net zero CO_2 emissions are reached (±420 $GtCO_2$) are separate.
*(3) Remaining carbon budget estimates consider the warming from non-CO_2 drivers as implied by the scenarios assessed in SR1.5. The Working Group III Contribution to AR6 will assess mitigation of non-CO_2 emissions.

D.1.3 Several factors that determine estimates of the remaining carbon budget have been re-assessed, and updates to these factors since SR1.5 are small. When adjusted for emissions since previous reports, estimates of remaining carbon budgets are therefore of similar magnitude compared to SR1.5 but larger compared to AR5 due to methodological improvements[44].
{5.5, Box 5.2, TS.3.3} **(Table SPM.2)**

D.1.4 Anthropogenic CO_2 removal (CDR) has the potential to remove CO_2 from the atmosphere and durably store it in reservoirs (*high confidence*). CDR aims to compensate for residual emissions to reach net zero CO_2 or net zero GHG emissions or, if implemented at a scale where anthropogenic removals exceed anthropogenic emissions, to lower surface temperature. CDR methods can have potentially wide-ranging effects on biogeochemical cycles and climate, which can either weaken or strengthen the potential of these methods to remove CO_2 and reduce warming, and can also influence water availability and quality, food production and biodiversity[45] (*high confidence*).
{5.6, Cross-Chapter Box 5.1, TS.3.3}

D.1.5 Anthropogenic CO_2 removal (CDR) leading to global net negative emissions would lower the atmospheric CO_2 concentration and reverse surface ocean acidification (*high confidence*). Anthropogenic CO_2 removals and emissions are partially compensated by CO_2 release and uptake respectively, from or to land and ocean carbon pools (*very high confidence*). CDR would lower atmospheric CO_2 by an amount approximately equal to the increase from an anthropogenic emission of the same magnitude (*high confidence*). The atmospheric CO_2 decrease from anthropogenic CO_2 removals could be up to 10% less than the atmospheric CO_2 increase from an equal amount of CO_2 emissions, depending on the total amount of CDR (*medium confidence*). {5.3, 5.6, TS.3.3}

D.1.6 If global net negative CO_2 emissions were to be achieved and be sustained, the global CO_2-induced surface temperature increase would be gradually reversed but other climate changes would continue in their current direction for decades to millennia (*high confidence*). For instance, it would take several centuries to millennia for global mean sea level to reverse course even under large net negative CO_2 emissions (*high confidence*).
{4.6, 9.6, TS.3.3}

D.1.7 In the five illustrative scenarios, simultaneous changes in CH_4, aerosol and ozone precursor emissions, that also contribute to air pollution, lead to a net global surface warming in the near and long-term (*high confidence*). In the long term, this net warming is lower in scenarios assuming air pollution controls combined with strong and sustained CH_4 emission reductions (*high confidence*). In the low and very low GHG emissions scenarios, assumed reductions in anthropogenic aerosol emissions lead to a net warming, while reductions in CH_4 and other ozone precursor emissions lead to a net cooling. Because of the short lifetime of both CH_4 and aerosols, these climate effects partially counterbalance each other and reductions in CH_4 emissions also contribute to improved air quality by reducing global surface ozone (*high confidence*).
{6.7, Box TS.7} **(Figure SPM.2, Box SPM.1)**

[44] Compared to AR5, and when taking into account emissions since AR5, estimates in AR6 are about 300–350 $GtCO_2$ larger for the remaining carbon budget consistent with limiting warming to 1.5°C; for 2°C, the difference is about 400–500 $GtCO_2$.

[45] Potential negative and positive effects of CDR for biodiversity, water and food production are methods-specific, and are often highly dependent on local context, management, prior land use, and scale. IPCC Working Groups II and III assess the CDR potential, and ecological and socio-economic effects of CDR methods in their AR6 contributions.

D.1.8 Achieving global net zero CO_2 emissions is a requirement for stabilizing CO_2-induced global surface temperature increase, with anthropogenic CO_2 emissions balanced by anthropogenic removals of CO_2. This is different from achieving net zero GHG emissions, where metric-weighted anthropogenic GHG emissions equal metric-weighted anthropogenic GHG removals. For a given GHG emission pathway, the pathways of individual greenhouse gases determine the resulting climate response[46], whereas the choice of emissions metric[47] used to calculate aggregated emissions and removals of different GHGs affects what point in time the aggregated greenhouse gases are calculated to be net zero. Emissions pathways that reach and sustain net zero GHG emissions defined by the 100-year global warming potential are projected to result in a decline in surface temperature after an earlier peak (*high confidence*).
{4.6, 7.6, Box 7.3, TS.3.3}

D.2 Scenarios with very low or low GHG emissions (SSP1-1.9 and SSP1-2.6) lead within years to discernible effects on greenhouse gas and aerosol concentrations, and air quality, relative to high and very high GHG emissions scenarios (SSP3-7.0 or SSP5-8.5). Under these contrasting scenarios, discernible differences in trends of global surface temperature would begin to emerge from natural variability within around 20 years, and over longer time periods for many other climatic impact-drivers (*high confidence*).

{4.6, Cross-Chapter Box 6.1, 6.6, 6.7, 9.6, Cross-Chapter Box 11.1, 11.2, 11.4, 11.5, 11.6, 12.4, 12.5} **(Figure SPM.8, Figure SPM.10)**

D.2.1 Emissions reductions in 2020 associated with measures to reduce the spread of COVID-19 led to temporary but detectible effects on air pollution (*high confidence*), and an associated small, temporary increase in total radiative forcing, primarily due to reductions in cooling caused by aerosols arising from human activities (*medium confidence*). Global and regional climate responses to this temporary forcing are, however, undetectable above natural variability (*high confidence*). Atmospheric CO_2 concentrations continued to rise in 2020, with no detectable decrease in the observed CO_2 growth rate (*medium confidence*)[48].
{Cross-Chapter Box 6.1, TS.3.3}

D.2.2 Reductions in GHG emissions also lead to air quality improvements. However, in the near term[49], even in scenarios with strong reduction of GHGs, as in the low and very low GHG emission scenarios (SSP1-2.6 and SSP1-1.9), these improvements are not sufficient in many polluted regions to achieve air quality guidelines specified by the World Health Organization (*high confidence*). Scenarios with targeted reductions of air pollutant emissions lead to more rapid improvements in air quality within years compared to reductions in GHG emissions only, but from 2040, further improvements are projected in scenarios that combine efforts to reduce air pollutants as well as GHG emissions with the magnitude of the benefit varying between regions (*high confidence*). {6.6, 6.7, Box TS.7}.

[46] A general term for how the climate system responds to a radiative forcing (see Glossary).

[47] The choice of emissions metric depends on the purposes for which gases or forcing agents are being compared. This report contains updated emission metric values and assesses new approaches to aggregating gases.

[48] For other GHGs, there was insufficient literature available at the time of the assessment to assess detectable changes in their atmospheric growth rate during 2020.

[49] Near term: (2021–2040)

D.2.3 Scenarios with very low or low GHG emissions (SSP1-1.9 and SSP1-2.6) would have rapid and sustained effects to limit human-caused climate change, compared with scenarios with high or very high GHG emissions (SSP3-7.0 or SSP5-8.5), but early responses of the climate system can be masked by natural variability. For global surface temperature, differences in 20-year trends would *likely* emerge during the near term under a very low GHG emission scenario (SSP1-1.9), relative to a high or very high GHG emission scenario (SSP3-7.0 or SSP5-8.5). The response of many other climate variables would emerge from natural variability at different times later in the 21st century (*high confidence*).
{4.6, Cross-Section Box TS.1} **(Figure SPM.8, Figure SPM.10)**

D.2.4 Scenarios with very low and low GHG emissions (SSP1-1.9 and SSP1-2.6) would lead to substantially smaller changes in a range of CIDs[36] beyond 2040 than under high and very high GHG emissions scenarios (SSP3-7.0 and SSP5-8.5). By the end of the century, scenarios with very low and low GHG emissions would strongly limit the change of several CIDs, such as the increase in the frequency of extreme sea level events, heavy precipitation and pluvial flooding, and exceedance of dangerous heat thresholds, while limiting the number of regions where such exceedances occur, relative to higher GHG emissions scenarios (*high confidence*). Changes would also be smaller in very low compared to low emissions scenarios, as well as for intermediate (SSP2-4.5) compared to high or very high emissions scenarios (*high confidence*). {9.6, Cross-Chapter Box 11.1, 11.2, 11.3, 11.4, 11.5, 11.6, 11.9, 12.4, 12.5, TS.4.3}

Introduction

The Working Group I (WGI) contribution to the Intergovernmental Panel on Climate Change Sixth Assessment Report (AR6) assess the physical science basis of climate change. As part of that contribution, this Technical Summary (TS) is designed to bridge between the comprehensive assessment of the WGI Chapters and its Summary for Policymakers (SPM). It is primarily built from the Executive Summaries of the individual chapters and atlas and provides a synthesis of key findings based on multiple lines of evidence (e.g., analyses of observations, models, paleoclimate information and understanding of physical, chemical and biological processes and components of the climate system). All the findings and figures here are supported by and traceable to the underlying chapters, with relevant chapter sections indicated in curly brackets.

Throughout this Technical Summary, key assessment findings are reported using the IPCC calibrated uncertainty language (Chapter 1, Box 1.1). Two calibrated approaches are used to communicate the degree of certainty in key findings, which are based on author teams' evaluations of underlying scientific understanding:

(1) Confidence[1] is a qualitative measure of the validity of a finding, based on the type, amount, quality and consistency of evidence (e.g., data, mechanistic understanding, theory, models, expert judgment) and the degree of agreement; and
(2) Likelihood[2] provides a quantified measure of confidence in a finding expressed probabilistically (e.g., based on statistical analysis of observations or model results, or both, and expert judgement by the author team or from a formal quantitative survey of expert views, or both).

Where there is sufficient scientific confidence, findings can also be formulated as statements of fact without uncertainty qualifiers. Throughout IPCC reports, the calibrated language is clearly identified by being typeset in italics.

The context and progress in climate science (TS.1) is followed by a Cross-Section Box TS.1 on global surface temperature change. TS.2 provides information about past and future large-scale changes in all components of the climate system. TS.3 summarises knowledge and understanding of climate forcings, feedbacks and responses. Infographic TS.1 uses a storyline approach to integrate findings on possible climate futures. Finally, TS.4 provides a synthesis of climate information at regional scales.[3] The list of acronyms used in the WGI Report is in Annex VIII.

The AR6 WGI report promotes best practices in traceability and reproducibility, including through adoption of the Findable, Accessible, Interoperable, and Reusable (FAIR) principles for scientific data. Each chapter has a data table (in its Supplementary Material) documenting the input data and code used to generate its figures and tables. In addition, a collection of data and code from the report has been made freely-available online via long-term archives. ([URL to access WGI data to be added by 30 June])

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[1] In this Technical Summary, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Chapter 1, Box 1.1 for more details).

[2] In this Technical Summary, the following terms have been used to indicate the assessed likelihood of an outcome or a result: *virtually certain* 99–100% probability, *very likely* 90–100%, likely 66–100%, *about as likely as not* 33–66%, *unlikely* 0–33%, *very unlikely* 0–10%, *exceptionally unlikely* 0–1%. Additional terms (extremely *likely*: 95–100%, *more likely than not* >50–100%, and *extremely unlikely* 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Chapter 1, Box 1.1 for more details). Throughout the WGI report and unless stated otherwise, uncertainty is quantified using 90% uncertainty intervals. The 90% uncertainty interval, reported in square brackets [x to y], is estimated to have a 90% likelihood of covering the value that is being estimated. The range encompasses the median value, and there is an estimated 10% combined likelihood of the value being below the lower end of the range (x) and above its upper end (y). Often the distribution will be considered symmetric about the corresponding best estimate, but this is not always the case. In this report, an assessed 90% uncertainty interval is referred to as a '*very likely* range'. Similarly, an assessed 66% uncertainty interval is referred to as a '*likely* range'.

[3] The regional trackback matrices that provide the location of the assessment findings synthesized in TS.4 are in the Supplementary Material (SM) for Chapter 10.

These FAIR principles are central to the WGI Interactive Atlas, an online tool that complements the WGI Report by providing flexible spatial and temporal analyses of past, observed and projected climate change information. ([URL to access WGI data to be added by 30 June]).

Regarding the representation of robustness and uncertainty in maps, the method chosen for the AR6[4] differs from the method used in the Sixth Assessment Report (AR5). This choice is based on new research in the visualization of uncertainty and on user surveys.

[START BOX TS.1 HERE]

Box TS.1: Core Concepts Central to This Report

This box provides short descriptions of key concepts which are relevant to the AR6 WGI assessment, with a focus on their use in the Technical Summary and the Summary for Policymakers. The Glossary (Annex VII) includes more information on these concepts along with definitions of many other important terms and concepts used in this Report.

Characteristics of Climate Change Assessment

***Global warming*:** Global warming refers to the change of global surface temperature relative to a baseline depending upon the application. Specific global warming levels, such as 1.5°C, 2°C, 3°C or 4°C, are defined as changes in global surface temperature relative to the years 1850–1900 as the baseline (the earliest period of reliable observations with sufficient geographic coverage). They are used to assess and communicate information about global and regional changes, linking to scenarios and used as a common basis for WGII and WGIII assessments. (TS.1.3, Cross-Section Box TS.1) {1.4.1, 1.6.2, 4.6.1, Cross-Chapter Boxes 1.5, 2.3, 11.1, and 12.1, Atlas.3-Atlas.11, Glossary}

***Emergence*:** Emergence refers to the experience or appearance of novel conditions of a particular climate variable in a given region. This concept is often expressed as the ratio of the change in a climate variable relative to the amplitude of natural variations of that variable (often termed a 'signal-to-noise' ratio, with emergence occurring at a defined threshold of this ratio). Emergence can be expressed in terms of a time or a global warming level at which the novel conditions appear and can be estimated using observations or model simulations. (TS.1.2.3, TS.4.2) {1.4.2, FAQ 1.2, 7.5.5, 10.3, 10.4, 12.5.2, Cross-Chapter Box Atlas.1, Glossary}

***Cumulative carbon dioxide (CO_2) emissions*:** The total net amount of CO_2 emitted into the atmosphere as a result of human activities. Given the nearly linear relationship between cumulative CO_2 emissions and increases in global surface temperature, cumulative CO_2 emissions are relevant for understanding how past and future CO_2 emissions affect global surface temperature. A related term – remaining carbon budget – is used to describe the total net amount of CO_2 that could be released in the future by human activities while keeping global warming to a specific global warming level, such as 1.5°C, taking into account the warming contribution from non-CO_2 forcers as well. The remaining carbon budget is expressed from a recent specified date, while the total carbon budget is expressed starting from the pre-industrial period. (TS.1.3, TS.3.4) {1.6.3, 5.5, Glossary}

***Net zero CO_2 emissions*:** A condition that occurs when the amount of CO_2 emitted into the atmosphere by human activities equals the amount of CO_2 removed from the atmosphere by human activities over a specified period of time. Net negative CO_2 emissions occur when anthropogenic removals exceed anthropogenic emissions. (TS.3.3) {Box 1.4, Glossary}

[4] The AR6 figures follow either one of the following approaches. For observations, the absence of 'x' symbols shows areas with statistical significance (while the presence of 'x' indicates non-significance). For model projections, the method offers two approaches with varying complexity. In the simple approach, high agreement (≥80%) is indicated with no overlay, and diagonal lines (///) shows low agreement (<80%); In the advanced approach, areas with no overlay display robust signal (≥66% of models show change greater than the variability threshold and ≥80% of all models agree on the sign of change), reverse diagonal lines (\\\) shows no robust signal, and crossed lines show conflicting signals (i.e., significant change but low agreement). Cross-Chapter Box Atlas.1 provides more information on the AR6 method for visualizing robustness and uncertainty on maps.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Human Influence on the Climate System

***Earth's energy imbalance*:** In a stable climate, the amount of energy that the Earth receives from the Sun is approximately in balance with the amount of energy that is lost to space in the form of reflected sunlight and thermal radiation. 'Climate drivers', such as an increase in greenhouse gases or aerosols, interfere with this balance, causing the system to either gain or lose energy. The strength of a climate driver is quantified by its effective radiative forcing (ERF), measured in W m^{-2}. Positive ERF leads to warming and negative ERF leads to cooling. That warming or cooling in turn can change the energy imbalance through many positive (amplifying) or negative (dampening) climate feedbacks. (TS.2.2, TS.3.1, TS.3.2) {2.2.8, 7.2, 7.3, 7.4, Box 7.1, Box 7.2, Glossary}

***Attribution*:** Attribution is the process of evaluating the relative contributions of multiple causal factors to an observed change in climate variables (e.g., global surface temperature, global mean sea level change), or to the occurrence of extreme weather or climate-related events. Attributed causal factors include human activities (such as increases in greenhouse gas concentration and aerosols, or land-use change) or natural external drivers (solar and volcanic influences), and in some cases internal variability. (TS.1.2.4, TS.2, Box TS.10) {Cross-Working Group Box: Attribution, 3.5, 3.8, 10.4, 11.2.4, Glossary}

***Committed change, long-term commitment*:** Changes in the climate system, resulting from past, present and future human activities, which will continue long into the future (centuries to millennia) even with strong reductions in greenhouse gas emissions. Some aspects of the climate system, including the terrestrial biosphere, deep ocean and the cryosphere, respond much more slowly than surface temperatures to changes in greenhouse gas concentrations. As a result, there are already substantial committed changes associated with past greenhouse gas emissions. For example, global mean sea level will continue to rise for thousands of years, even if future CO_2 emissions are reduced to net zero and global warming halted, as excess energy due to past emissions continues to propagate into the deep ocean and as glaciers and ice sheets continue to melt. (TS.2.1, Box TS.4, Box TS.9) {1.2.1, 1.3, Box 1.2, Cross-Chapter Box 5.3}

Climate Information for Regional Climate Change and Risk Assessment

***Distillation*:** The process of synthesizing information about climate change from multiple lines of evidence obtained from a variety of sources, taking into account user context and values. It leads to an increase in the usability, usefulness, and relevance of climate information, enhances stakeholder trust, and expands the foundation of evidence used in climate services. It is particularly relevant in the context of co-producing regional-scale climate information to support decision-making. (TS.4.1, Box TS.11) {10.1, 10.5, 12.6}

***(Climate change) risk*:** The concept of risk is a key aspect of how the IPCC assesses and communicates to decision-makers about the potential for adverse consequences for human or ecological systems, recognising the diversity of values and objectives associated with such systems. In the context of climate change, risks can arise from potential impacts of climate change as well as human responses to climate change. WGI contributes to the common IPCC risk framing through the assessment of relevant climate information, including climatic impact-drivers and low-likelihood, high impact outcomes. (TS.1.4, TS.4.1, Box TS.4) {Cross-Chapter Boxes 1.3 and 12.1, Glossary}

***Climatic impact-drivers*:** Physical climate system conditions (e.g., means, events, extremes) that can be directly connected with having impacts on human or ecological systems are described as 'climatic impact-drivers' (CIDs) without anticipating whether their impacts are detrimental (i.e., as for hazards in the context of climate change risks) or provide potential opportunities. A range of indices may capture the sector- or application-relevant characteristics of a climatic impact-driver and can reflect exceedances of identified tolerance thresholds. (TS.1.4, TS.4.3) {12.1-12.3, FAQ12.1, Glossary}

***Storylines*:** The term storyline is used both in connection to scenarios (related to a future trajectory of emissions or socio-economic developments) or to describe plausible trajectories of weather and climate conditions or events, especially those related to high levels of risk. Physical climate storylines are introduced in AR6 to explore uncertainties in climate change and natural climate variability, to develop and communicate integrated

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and context-relevant regional climate information, and to address issues with deep uncertainty[5], *including low-likelihood, high-impact outcomes.* (TS.1.4, Box TS.3, Infographic TS.1) {1.4.4, Box 10.2, Glossary}

***Low-likelihood, high impact outcomes*:** Events whose probability of occurrence is low or not well known (as in the context of deep uncertainty) but whose potential impacts on society and ecosystems could be high. To better inform risk assessment and decision-making, such low-likelihood outcomes are considered if they are associated with very large consequences and may therefore constitute material risks, even though those consequences do not necessarily represent the most likely outcome. (TS.1.4, Box TS.3, Figure TS.6) {1.4.4, 4.8, Cross Chapter Box 1.3, Glossary}

[END BOX TS.1 HERE]

As part of the AR6 cycle, the IPCC produced three Special Reports in 2018 and 2019: the Special Report on Global Warming of 1.5°C (SR1.5), the Special Report on Oceans and Cryosphere in a Changing Climate (SROCC), and the Special Report on Climate Change and Land (SRCCL).

The AR6 WGI Report provides a full and comprehensive assessment of the physical science basis of climate change that builds on the previous assessments and these Special Reports and consider new information and knowledge from the recent scientific literature[6], including longer observational datasets, new scenarios and model results.

The structure of the AR6 WGI report is designed to enhance the visibility of knowledge developments and to facilitate the integration of multiple lines of evidence, thereby improving confidence in findings. The Report has been peer-reviewed by the scientific community and governments (Annex X provides the Expert Reviewer list). The substantive introduction provided by Chapter 1 is followed by a first set of chapters dedicated to large-scale climate knowledge (Chapters 2–4), which encompasses observations and paleoclimate evidence, causes of observed changes, and projections, and are complemented by Chapter 11 for large-scale changes in extremes. The second set of chapters (Chapters 5–9) is orientated around the understanding of key climate system components and processes, including the global cycles of carbon, energy and water; short-lived climate forcers and their link to air quality; the ocean, cryosphere and sea level change. The last set of chapters (Chapters 10–12 and the Atlas) is dedicated to the assessment and distillation of regional climate information from multiple lines of evidence at sub-continental to local scales (including urban climate), with a focus on recent and projected regional changes in mean climate, extremes, and climatic impact-drivers. The new online Interactive Atlas allows users to interact in a flexible manner through maps, time series and summary statistics with climate information for a set of updated WGI reference regions. The Report also includes 34 Frequently Asked Questions and answers for the general public. [URL to access FAQs to be added by 30 June]

Together, this Technical Summary and the underlying chapters aim at providing a comprehensive picture of knowledge progress since the WGI AR5. Multiple lines of scientific evidence confirm that the climate is changing due to human influence. Important advances in the ability to understand past, present, and possible future changes should result in better-informed decision-making.

Some of the new results and main updates to key findings in AR6 WGI compared to AR5, SR1.5, SRCCL, and SROCC are summarized below. Relevant Technical Summary sections with further details are shown in

[5] Although not a core concept of the WGI Report, deep uncertainty is used in the Technical Summary in the following sense: 'A situation of deep uncertainty exists when experts or stakeholders do not know or cannot agree on: (1) appropriate conceptual models that describe relationships among key driving forces in a system; (2) the probability distributions used to represent uncertainty about key variables and parameters; and/or (3) how to weigh and value desirable alternative outcomes' (Lempert et al., 2003). Lempert, R. J., Popper, S. W., and Bankes, S. C. (2003). *Shaping the next one hundred years: New methods for quantitative long-term strategy analysis (MR-1626-RPC)*. Santa Monica, CA: The RAND Pardee Center.

[6] The assessment covers scientific literature accepted for publication by 31 January 2021.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

parenthesis after each bullet point.

Selected Updates and/or New Results since AR5

- **Human influence[7] on the climate system is now an established fact:** The Fourth Assessment Report (AR4) stated in 2007 that 'warming of the climate system is unequivocal', and the AR5 stated in 2013 that 'human influence on the climate system is clear'. Combined evidence from across the climate system strengthens this finding. It is unequivocal that the increase of CO_2, methane (CH_4) and nitrous oxide (N_2O) in the atmosphere over the industrial era is the result of human activities and that human influence is the principal driver of many changes observed across the atmosphere, ocean, cryosphere and biosphere. (TS.1.2, TS.2.1)
- **Observed global warming to date:** A combination of improved observational records and a series of very warm years since AR5 have resulted in a substantial increase in the estimated level of global warming to date. The contribution of changes in observational understanding alone between AR5 and AR6 leads to an increase of about 0.1°C in the estimated warming since 1850–1900. For the decade 2011–2020, the increase in global surface temperature since 1850–1900 is assessed to be 1.09 [0.95 to 1.20] °C.[8] Estimates of crossing times of global warming levels and estimates of remaining carbon budgets are updated accordingly. (TS.1.2, Cross-Section Box TS.1)
- **Paleoclimate evidence:** The AR5 assessed that many of the changes observed since the 1950s are unprecedented over decades to millennia. Updated paleoclimate evidence strengthens this assessment; over the past several decades, key indicators of the climate system are increasingly at levels unseen in centuries to millennia and are changing at rates unprecedented in at least the last 2000 years. (Box TS.2, TS.2)
- **Updated assessment of recent warming:** The AR5 reported a smaller rate of increase in global mean surface temperature over the period 1998–2012 than the rate calculated since 1951**.** Based on updated observational datasets showing a larger trend over 1998–2012 than earlier estimates, there is now *high confidence* that the observed 1998–2012 global surface temperature trend is consistent with ensembles of climate model simulations, and there is now *very high confidence* that the slower rate of global surface temperature increase observed over this period was a temporary event induced by internal and naturally forced variability that partly offset the anthropogenic surface warming trend over this period, while heat uptake continued to increase in the ocean. Since 2012, strong warming has been observed, with the past five years (2016–2020) being the hottest five-year period in the instrumental record since at least 1850 (*high confidence*). (TS.1.2, Cross-Section Box TS.1)
- **Magnitude of climate system response:** In this Report, it has been possible to reduce the long-standing uncertainty ranges for metrics that quantify the response of the climate system to radiative forcing, such as the equilibrium climate sensitivity (ECS) and the transient climate response (TCR), due to substantial advances (e.g., a 50% reduction in the uncertainty range of cloud feedbacks) and improved integration of multiple lines of evidence, including paleoclimate information. Improved quantification of effective radiative forcing, the climate system radiative response, and the observed energy increase in the Earth system over the past five decades demonstrate improved consistency between independent estimates of climate drivers, the combined climate feedbacks, and the observed energy increase relative to AR5. (TS.3.2)
- **Improved constraints on projections of future climate change:** For the first time in an IPCC report, the assessed future change in global surface temperature is consistently constructed by combining scenario-based projections (which the AR5 focused on) with observational constraints based on past simulations of warming as well as the updated assessment of ECS and TCR. In addition, initialized forecasts have been used for the period 2019–2018. The inclusion of these lines of evidence reduces the assessed uncertainty for each scenario. (TS.1.3, Cross-Section Box TS.1)

[7] Human influence on the climate system refers to human-driven activities that lead to changes in the climate system due to perturbations of the Earth's energy budget (also called anthropogenic forcing). Human influence results from emissions of greenhouse gases, aerosols and tropospheric ozone precursors, ozone-depleting substances, and land-use change.

[8] Throughout the WGI report and unless stated otherwise, uncertainty is quantified using 90% uncertainty intervals. The 90% uncertainty interval, reported in square brackets [x to y], is estimated to have a 90% likelihood of covering the value that is being estimated. The range encompasses the median value and there is an estimated 10% combined likelihood of the value being below the lower end of the range (x) and above its upper end (y). Often the distribution will be considered symmetric about the corresponding best estimate, but this is not always the case. In this report, an assessed 90% uncertainty interval is referred to as a '*very likely* range'. Similarly, an assessed 66% uncertainty interval is referred to as a '*likely* range'

ACCEPTED VERSION SUBJECT TO FINAL EDITING

- **Air quality:** The AR5 assessed that projections of air quality are driven primarily by precursor emissions, including methane. New scenarios explore a diversity of future options in air pollution management. The AR6 WGI reports rapid recent shifts in the geographical distribution of some of these precursor emissions, confirms the AR5 finding, and shows higher warming effects of short-lived climate forcers in scenarios with the highest air pollution. (TS.1.3, TS.2.2, Box TS.7)
- **Effects of short-lived climate forcers on global warming:** The AR5 assessed the radiative forcing for emitted compounds. The AR6 has extended this by assessing the emission-based effective radiative forcings (ERFs) also accounting for aerosol–cloud interactions. The best estimates of ERF attributed to sulphur dioxide (SO_2) and CH_4 emissions are substantially greater than in AR5, while that of black carbon is substantially reduced. The magnitude of uncertainty in the ERF due to black carbon emissions has also been reduced relative to AR5.
- **Global water cycle:** The AR5 assessed that anthropogenic influences have *likely* affected the global water cycle since 1960. The dedicated chapter in the AR6 WGI (Chapter 8) concludes with *high confidence* that human-caused climate change has driven detectable changes in the global water cycle since the mid-20th century, with a better understanding of the response to aerosol and greenhouse gas changes. The AR6 WGI further projects with *high confidence* an increase in the variability of the water cycle in most regions of the world and under all emissions scenarios (Box TS.6)
- **Extreme events**: The AR5 assessed that human influence had been detected in changes in some climate extremes. A dedicated chapter in the AR6 (Chapter 11) concludes that it is now an established fact that human-induced greenhouse gas emissions have led to an increased frequency and/or intensity of some weather and climate extremes since 1850, in particular for temperature extremes. Evidence of observed changes and attribution to human influence has strengthened for several types of extremes since AR5, in particular for extreme precipitation, droughts, tropical cyclones and compound extremes (including fire weather). (TS.1.2, TS.2.1)

Selected Updates and/or New Results Since AR5 and SR1.5

- **Timing of crossing 1.5°C global warming:** Slightly different approaches are used in SR1.5 and in this Report. SR1.5 assessed a *likely* range of 2030 to 2052 for reaching a global warming level of 1.5°C (for a 30-year period), assuming a continued, constant rate of warming. In AR6, combining the larger estimate of global warming to date and the assessed climate response to all considered scenarios, the central estimate of crossing 1.5°C of global warming (for a 20-year period) occurs in the early 2030s, ten years earlier than the midpoint of the *likely* range assessed in the SR1.5, assuming no major volcanic eruption. (TS.1.3, Cross-Section Box TS.1)
- **Remaining carbon budgets:** The AR5 had assessed the transient climate response to cumulative emissions of CO_2 to be *likely* in the range of 0.8°C to 2.5°C per 1000 GtC (1 GtC = 1 PgC = 3.667 $GtCO_2$), and this was also used in SR1.5. The assessment in AR6, based on multiple lines of evidence, leads to a narrower *likely* range of 1.0°C–2.3°C per 1000 GtC. This has been incorporated in updated estimates of remaining carbon budgets (see TS.3.3.1), together with methodological improvements and recent observations. (TS.1.3, TS.3.3)
- **Effect of short-lived climate forcers on global warming in coming decades:** The SR1.5 stated that reductions in emissions of cooling aerosols partially offset greenhouse gas mitigation effects for two to three decades in pathways limiting global warming to 1.5°C. The AR6 assessment updates the AR5 assessment of the net cooling effect of aerosols and confirms that changes in short-lived climate forcers will *very likely* cause further warming in the next two decades across all scenarios (TS.1.3, Box TS.7)
- **COVID-19**: Temporary emission reductions in 2020 associated with COVID-19 containment led to small and positive net radiative effect (warming influence). However, global and regional climate responses to this forcing are undetectable above internal climate variability due to the temporary nature of emission reductions. (TS.3.3)

Selected Updates and/or New Results Since AR5, SRCCL and SROCC

- **Atmospheric concentration of methane:** SRCCL reported a resumption of atmospheric methane

ACCEPTED VERSION SUBJECT TO FINAL EDITING

concentration growth since 2007. WGI AR6 reports a faster growth over 2014–2019 and assesses growth since 2007 to be largely driven by emissions from the fossil fuels and agriculture (dominated by livestock) sectors. (TS.2.2)

- **Land and ocean carbon sinks:** SRCCL assessed that the persistence of the land carbon sink is uncertain due to climate change. WGI AR6 finds that land and ocean carbon sinks are projected to continue to grow until 2100 with increasing atmospheric concentrations of CO_2, but the fraction of emissions taken up by land and ocean is expected to decline as the CO_2 concentration increases, with a much larger uncertainty range for the land sink. AR5, SR1.5 and SRCCL assessed carbon dioxide removal options and scenarios. WGI AR6 finds that the carbon cycle response is asymmetric for pulse emissions or removals, which means that CO_2 emissions would be more effective at raising atmospheric CO_2 than CO_2 removals are at lowering atmospheric CO_2. (TS.3.3, Box TS.5)
- **Ocean stratification increase[9]:** Refined analyses of available observations in the AR6 lead to a reassessment of the rate of increase of the global stratification in the upper 200 m to be double that estimated in SROCC from 1970 to 2018. (TS.2.4)
- **Projected ocean oxygen loss:** Future subsurface oxygen decline in new projections assessed in WGI AR6 is substantially greater in 2080–2099 than assessed in SROCC. (TS.2.4)
- **Ice loss from glaciers and ice sheets:** since SROCC, globally resolved glacier changes have improved estimates of glacier mass loss over the past 20 years, and estimates of the Greenland and Antarctic Ice Sheet loss have been extended to 2020. (TS.2.5)
- **Observed global mean sea level change:** new observation-based estimates published since SROCC lead to an assessed sea level rise estimate from 1901 to 2018 that is now consistent with the sum of individual components and consistent with closure of the global energy budget. (Box TS.4)
- **Projected global mean sea level change:** AR6 projections of global mean sea level are based on projections from ocean thermal expansion and land ice contribution estimates, which are consistent with the assessed equilibrium climate sensitivity and assessed changes in global surface temperature. They are underpinned by new land ice model intercomparisons and consideration of processes associated with l*ow confidence* to characterise the deep uncertainty in future ice loss from Antarctica. AR6 projections based on new models and methods are broadly consistent with SROCC findings. (Box TS.4)

[9] Increased stratification reduces the vertical exchange of heat, salinity, oxygen, carbon, and nutrients. Stratification is an important indicator for ocean circulation.

TS.1 A Changing Climate

This section introduces the assessment of the physical science basis of climate change in the AR6 and presents the climate context in which this assessment takes place, recent progress in climate science and the relevance of global and regional climate information for impact and risk assessments. The future emissions scenarios and global warming levels, used to integrate assessments across WGI AR6, are introduced and their applications for future climate projections are briefly addressed. Paleoclimate science provides a long-term context for observed climate change of the past 150 years and the projected changes in the 21st century and beyond (Box TS.2). The assessment of past, current and future global surface temperature changes relative to the standard baselines and reference periods[10] used throughout this Report is summarized in Cross-Section Box TS.1.

TS.1.1 Context of a Changing Climate

AR6 WGI assesses new scientific evidence relevant for a world whose climate system is rapidly changing, overwhelmingly due to human influence. The five IPCC assessment cycles since 1990 have comprehensively and consistently laid out the rapidly accumulating evidence of a changing climate system, with the Fourth Assessment Report (AR4) in 2007 being the first to conclude that warming of the climate system is unequivocal. Sustained changes have been documented in all major elements of the climate system: the atmosphere, land, cryosphere, biosphere and ocean (TS.2). Multiple lines of evidence indicate the recent large-scale climatic changes are unprecedented in a multi-millennial context, and that they represent a millennial-scale commitment for the slow-responding elements of the climate system, resulting in continued worldwide loss of ice, increase in ocean heat content, sea level rise and deep ocean acidification (Box TS.2; Section TS.2). {1.2.1, 1.3, Box 1.2, 2.2, 2.3, Figure 2.34, 5.1, 5.3, 9.2, 9.4-9.6, Appendix 1.A}

Earth's climate system has evolved over many millions of years, and evidence from natural archives provides a long-term perspective on observed and projected changes over the coming centuries. These reconstructions of past climate also show that atmospheric CO_2 concentrations and global surface temperature are strongly coupled (Figure TS.1), based on evidence from a variety of proxy records over multiple time scales (Box TS.2; TS.2). Levels of global warming (see Core Concepts Box) that have not been seen in millions of years could be reached by 2300, depending on the emissions pathway that is followed (TS.1.3). For example, there is *medium confidence* that, by 2300, an intermediate scenario[11] used in the report leads to global surface temperatures of 2.3°C–4.6°C higher than 1850–1900, similar to the mid-Pliocene Warm Period (2.5°C–4°C), about 3.2 million years ago, whereas the high CO_2 emissions scenario SSP5-8.5 leads to temperatures of 6.6°C–14.1°C by 2300, which overlaps with the Early Eocene Climate Optimum (10°C–18°C), about 50 million years ago. {Cross-Chapter Box 2.1 and 2.4, 2.3.1, 4.3.1.1, 4.7.1.2, 7.4.4.1}

[START FIGURE TS.1 HERE]

Figure TS.1: Changes in atmospheric CO_2 and global surface temperature (relative to 1850-1900) from the deep past to the next 300 years. *The intent is to show that CO_2 and temperature covary, both in the past and into the future, and that projected CO_2 and temperatures are similar to those only from many millions of years ago.* CO_2 concentrations from millions of years ago are reconstructed from multiple proxy records (grey dots are data from 2.2.3.1, Figure 2.3 shown with cubic-spline fit). CO_2 levels for the last 800,000 years through the mid-20th century are from air trapped in polar ice; recent values are

[10] Several baselines or reference periods are used consistently throughout AR6 WGI. Baseline refers to a period against which anomalies (i.e., differences from the average value for the baseline period) are calculated. Examples include the 1750 baseline (used for anthropogenic radiative forcings), the 1850–1900 baseline (an approximation for pre-industrial global surface temperature from which global warming levels are calculated) and the 1995–2014 baseline (used for many climate model projections). A reference period indicates a time period over which various statistics are calculated (e.g., the near-term reference period, 2021–2040). Paleo reference periods are listed in Box TS.2. {1.4.1, Cross-Chapter Box 1.2 and 2.1}

[11] Please refer to Section TS.1.3.1 for an overview of the climate change scenarios used in this report.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

from direct air measurements (Figure TS.9). {1.2.1.2, 2.2.3, Figures 1.5, 2.4, 2.5} Global surface temperature prior to 1850 is estimated from marine oxygen isotopes, one of multiple sources of evidence used to assess paleo temperatures in this report. {2.3.1.1.1, Cross-Chapter Box 2.1, Figure 1} Temperature of the past 170 years is the AR6 assessed mean (Cross-Section Box TS.1). {2.3.1.1} CO_2 levels and global surface temperature change for the future are shown for three SSP scenarios (TS.1.3) through 2300 CE, using Earth System Model emulators calibrated to the assessed global surface temperatures. {4.7.1, Cross-Chapter Box 7.1} Their smooth trajectories do not account for inter-annual to inter-decadal variability, including transient response to potential volcanic eruptions. {Cross-Chapter Box 4.1} Global maps for two paleo reference periods are based on CMIP6 and pre-CMIP6 multi-model means, with site-level proxy data for comparison (squares and circles are marine and terrestrial, respectively) (Box TS.2). {Cross-Chapter Box 2.1, Figure 7.13} The map for 2020 is an estimate of the total observed warming since 1850-1900. {Figure 1.14} Global maps at right show two SSP scenarios at 2100 (2081-2100) {4.5.1} and at 2300 (2281-2300; map from CMIP6 models; temperature assessed in 4.7.1). A brief account of the major climate forcings associated with past global temperature changes is in Cross-Chapter Box 2.1.

[END FIGURE TS.1 HERE]

Understanding of the climate system's fundamental elements is robust and well established. Scientists in the 19th century identified the major natural factors influencing the climate system. They also hypothesized the potential for anthropogenic climate change due to carbon dioxide (CO_2) emitted by combustion of fossil fuels (petroleum, coal, natural gas). The principal natural drivers of climate change, including changes in incoming solar radiation, volcanic activity, orbital cycles, and changes in global biogeochemical cycles, have been studied systematically since the early 20th century. Other major anthropogenic drivers, such as atmospheric aerosols (fine solid particles or liquid droplets), land-use change and non-CO_2 greenhouse gases, were identified by the 1970s. Since systematic scientific assessments began in the 1970s, the influence of human activity on the warming of the climate system has evolved from theory to established fact (see also TS.2). The evidence for human influence on recent climate change strengthened from the IPCC First Assessment Report in 1990 to the IPCC Fifth Assessment Report in 2013/14, and is now even stronger in this assessment (TS.1.2.4, TS.2). Changes across a greater number of climate system components, including changes in regional climate and extremes can now be attributed to human influence (see TS.2 and TS.4). {1.3.1 - 1.3.5, 3.1, 11.2, 11.9}

[START BOX TS.2 HERE]

Box TS.2: Paleoclimate

Paleoclimate evidence is integrated within multiple lines of evidence across the WGI report to more fully understand the climate system. Paleo evidence extends instrument-based observations of climate variables and climate drivers back in time, providing the long-term context needed to gauge the extent to which recent and potential future changes are unusual (TS.2, Figure TS.1). Pre-industrial climate states complement evidence from climate model projections by providing real-world examples of climate characteristics for past global warming levels, with empirical evidence for how the slow-responding components of the climate system operate over centuries to millennia – the time scale for committed climate change (Core Concepts Box, Box TS.4, Box TS.9). Information about the state of the climate system during well-described paleoclimate reference periods helps narrow the uncertainty range in the overall assessment of Earth's sensitivity to climate forcing (TS.3.2.1). {Cross-Chapter Box 2.1, FAQ 1.3, FAQ 2.1}

Paleoclimate reference periods. Over the long evolution of the Earth's climate, several periods have received extensive research attention as examples of distinct climate states and rapid climate transitions (Box TS.2, Figure 1). These paleoclimate reference periods represent the present geological era (Cenozoic; past 65 million years) and are used across chapters to help structure the assessment of climate changes prior to industrialization. Cross-Chapter Box 2.1 describes the reference periods, along with a brief account of their climate forcings, and lists where each is discussed in other chapters. Cross-Chapter Box 2.4 summarizes

ACCEPTED VERSION SUBJECT TO FINAL EDITING

information on one of the reference periods, the mid-Pliocene Warm Period. The Interactive Atlas includes model output from the World Climate Research Programme Coupled Model Intercomparison Project Phase 6 (CMIP6) for four of the paleoclimate reference periods.

[START BOX TS.2, FIGURE 1 HERE]

Box TS.2, Figure 1: Paleoclimate and recent reference periods, with selected key indicators. *The intent of this figure is to list the paleoclimate reference periods used in the WGI report, to summarize three key global climate indicators, and compare CO_2 with global temperature over multiple periods*. (a) Three large-scale climate indicators (atmospheric CO_2, global surface temperature relative to 1850-1900, and global mean sea level relative to 1900), based on assessments in Chapter 2, with confidence levels ranging from *low* to *very high*. (b) Comparison between global surface temperature (relative to 1850-1900) and atmospheric CO_2 concentration for multiple reference periods (mid-points with 5–95% ranges). {2.2.3, 2.3.1.1, 2.3.3.3, Figure 2.34}

[END BOX TS.2, FIGURE 1 HERE]

Paleoclimate models and reconstructions. Climate models that target paleoclimate reference periods have been featured by the IPCC since the First Assessment Report. Under the framework of CMIP6-PMIP4 (Paleoclimate Modelling Intercomparison Project), new protocols for model intercomparisons have been developed for multiple paleoclimate reference periods. These modelling efforts have led to improved understanding of the climate response to different external forcings, including changes in Earth's orbital and plate movements, solar irradiance, volcanism, ice-sheet size, and atmospheric greenhouse gases. Likewise, quantitative reconstructions of climate variables from proxy records that are compared with paleoclimate simulations have improved as the number of study sites and variety of proxy types have expanded, and as records have been compiled into new regional and global datasets. {1.3.2, 1.5.1, Cross-Chapter Boxes 2.1 and 2.4}

Global surface temperature. Since AR5, updated climate forcings, improved models, new understanding of the strengths and weaknesses of a growing array of proxy records, better chronologies, and more robust proxy data products have led to better agreement between models and reconstructions. For global surface temperature, the mid-point of the AR6-assessed range and the median of the model-simulated temperatures differ by an average of 0.5°C across five reference periods; they overlap within their 90% ranges in four of five cases, which together span from about 6°C [5–7]°C colder during the Last Glacial Maximum to about 14 [10 to 18] °C warmer during the Early Eocene, relative to 1850–1900 (Box TS.2, Figure 2a). Changes in temperature by latitude in response to multiple forcings show that polar amplification (stronger warming at high latitudes than the global average) is a prominent feature of the climate system across multiple climate states, and the ability of models to simulate this polar amplification in past warm climates has improved since AR5 (*high confidence*). Over the past millennium, and especially since about 1300 CE, simulated global surface temperature anomalies are well within the uncertainty of reconstructions (*medium confidence*), except for some short periods immediately following large volcanic eruptions, for which different forcing datasets disagree (Box TS.2, Figure 2b). {2.3.1.1, 3.3.3.1, 3.8.2.1, 7.4.4.1.2}

[START BOX TS.2, FIGURE 2 HERE]

Box TS.2, Figure 2: Global surface temperature as estimated from proxy records (reconstructed) and climate models (simulated). *The intent of this figure is to show the agreement between observations and models of global temperatures during paleo reference periods*. (a) For individual paleoclimate reference periods. (b) For the last millennium, with instrumental temperature (AR6 assessed mean,10-year smoothed). Model uncertainties in (a) and (b) are 5-95% ranges of multi-model ensemble means; reconstructed uncertainties are 5-95% ranges (*medium confidence*) of (a) midpoints and (b) multi-method ensemble median. {2.3.1.1, Figure 2.34, Figure 3.2c, Figure 3.44}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END BOX TS.2, FIGURE 2 HERE]

Equilibrium climate sensitivity. Paleoclimate data provide evidence to estimate equilibrium climate sensitivity (ECS[12]) (TS.3.2.1). In AR6, refinements in paleo data for paleoclimate reference periods indicate that ECS is *very likely* greater than 1.5°C and *likely* less than 4.5°C, which is largely consistent with other lines of evidence and helps narrow the uncertainty range of the overall assessment of ECS. Some of the CMIP6 climate models that have either high (> 5°C) or low (< 2°C) ECS also simulate past global surface temperature changes outside the range of proxy-based reconstructions for the coldest and warmest reference periods. Since AR5, independent lines of evidence, including proxy records from past warm periods and glacial-interglacial cycles, indicate that sensitivity to forcing increases as temperature increases (TS.3.2.2). {7.4.3.2, 7.5.3, 7.5.6, Table 7.11}

Water cycle. New hydroclimate reconstructions and model-data comparisons have improved the understanding of the causes and effects of long-term changes in atmospheric and ocean circulation, including monsoon variability and modes of variability (Box TS.13, TS.4.2). Climate models are able to reproduce decadal drought variability on large regional scales, including the severity, persistence and spatial extent of past megadroughts known from proxy records (*medium confidence*). Some long-standing discrepancies remain, however, such as the magnitude of African monsoon precipitation during the early Holocene, suggesting continuing knowledge gaps. Paleoclimate evidence shows that, in relatively high CO_2 climates such as the Pliocene, Walker circulation over the equatorial Pacific Ocean weakens, supporting the *high confidence* model projections of weakened Walker cells by the end of the 21st century. {3.3.2, 8.3.1.6, 8.4.1.6, 8.5.2.1, 9.2}

Sea level and ice sheets. Although past and future global warming differ in their forcings, evidence from paleoclimate records and modelling show that ice sheet mass and global mean sea level (GMSL) responded dynamically over multiple millennia (*high confidence*). This evidence helps to constrain estimates of the committed GMSL response to global warming (Box TS.4). For example, under a past global warming levels of around 2.5°C–4°C relative to 1850–1900, like during the mid-Pliocene Warm Period, sea level was 5–25 m higher than 1900 (*medium confidence*); under past global warming levels of 10°C–18°C, like during the Early Eocene, the planet was essentially ice free (*high confidence*). Constraints from these past warm periods, combined with physical understanding, glaciology and modelling, indicate a committed long-term GMSL rise over 10,000 years, reaching about 8–13 m for sustained peak global warming of 2°C and to 28–37 m for 5°C, which exceeds the AR5 estimate. {2.3.3.3, 9.4.1.4, 9.4.2.6, 9.6.2, 9.6.3.5}

Ocean. Since AR5, better integration of paleo-oceanographic data with modelling along with higher-resolution analyses of transient changes have improved understanding of long-term ocean processes. Low-latitude sea-surface temperatures at the Last Glacial Maximum cooled more than previously inferred, resolving some inconsistencies noted in AR5. This paleo context supports the assessment that ongoing increase in ocean heat content (OHC) represents a long-term commitment (see Core Concepts Box), essentially irreversible on human time scales (*high confidence*). Estimates of past global OHC variations generally track those of sea surface temperatures around Antarctica, underscoring the importance of Southern Ocean processes in regulating deep-ocean temperatures. Paleoclimate data, along with other evidence of glacial-interglacial changes, show that Antarctic Circumpolar flow strengthened and that ventilation of Antarctic Bottom Water accelerated during warming intervals, facilitating release of CO_2 stored in the deep ocean to the atmosphere. Paleo evidence suggests significant reduction of deep-ocean ventilation associated with meltwater input during times of peak warmth. {2.3.1.1, 2.3.3.1, 9.2.2, 9.2.3.2}

Carbon cycle. Past climate states were associated with substantial differences in the inventories of the various carbon reservoirs, including the atmosphere (TS.2.2). Since AR5, the quantification of carbon stocks has improved due to the development of novel sedimentary proxies and stable-isotope analyses of air trapped in polar ice. Terrestrial carbon storage decreased markedly during the Last Glacial Maximum by 300–600

[12] In this report, equilibrium climate sensitivity is defined as the equilibrium (steady state) change in the surface temperature following a doubling of the atmospheric carbon dioxide (CO_2) concentration from pre-industrial conditions.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

PgC, possibly by 850 PgC when accounting for interactions with the lithosphere and ocean sediments, a larger reduction than previously estimated, owing to colder and drier climate. At the same time, the storage of remineralised carbon in the ocean interior increased by as much as 750–950 PgC, sufficient to balance the removal of carbon from the atmosphere (200 PgC) and terrestrial biosphere reservoirs combined (*high confidence*). {5.1.2.2}

[END BOX TS.2 HERE]

TS.1.2 Progress in Climate Science

TS.1.2.1 Observation-based products and their assessments

Observational capabilities have continued to improve and expand overall since AR5, enabling improved consistency between independent estimates of climate drivers, the combined climate feedbacks, and the observed energy and sea level increase. Satellite climate records and improved reanalyses are used as an additional line of evidence for assessing changes at the global and regional scales. However, there have also been reductions in some observational data coverage or continuity and limited access to data resulting from data policy issues. Natural archives of past climate, such as tropical glaciers, have also been subject to losses (in part due to anthropogenic climate change). {1.5.1, 1.5.2, 10.2.2}

Earth system observations are an essential driver of progress in our understanding of climate change. Overall, capabilities to observe the physical climate system have continued to improve and expand. Improvements are particularly evident in ocean observing networks and remote sensing systems. Records from several recently instigated satellite measurement techniques are now long enough to be relevant for climate assessments. For example, globally distributed, high-vertical-resolution profiles of temperature and humidity in the upper troposphere and stratosphere can be obtained from the early 2000s using global navigation satellite systems, leading to updated estimates of recent atmospheric warming. Improved measurements of ocean heat content, warming of the land surface, ice sheet mass loss, and sea level changes allow a better closure of the global energy and sea level budgets relative to AR5. For surface and balloon-based networks, apparent regional data reductions result from a combination of data policy issues, data curation/provision challenges, and real cessation of observations, and are to an extent counter-balanced by improvements elsewhere. Limited observational records of extreme events and spatial data gaps currently limit the assessment of some observed regional climate change. {1.5.1, 2.3.2, 7.2.2, Box 7.2, Cross-Chapter Box 9.1, 9.6.1, 10.2.2, 10.6, 11.2, 12.4}

New paleoclimate reconstructions from natural archives have enabled more robust reconstructions of the spatial and temporal patterns of past climate changes over multiple time scales (Box TS.2). However, paleoclimate archives, such as tropical glaciers and modern natural archives used for calibration (e.g., corals and trees), are rapidly disappearing owing to a host of pressures, including increasing temperatures (*high confidence*). Substantial quantities of past instrumental observations of weather and other climate variables, over both land and ocean, which could fill gaps in existing datasets, remain un-digitized or inaccessible. These include measurements of temperature (air and sea surface), rainfall, surface pressure, wind strength and direction, sunshine amount and many other variables dating back into the 19th century. {1.5.1}

Reanalyses combine observations and models (e.g., a numerical weather prediction model) using data assimilation techniques to provide a spatially complete, dynamically consistent estimate of multiple variables describing the evolving climate state. Since AR5, new reanalyses have been developed for the atmosphere and the ocean with various combinations of increased resolution, extended records, more consistent data assimilation and larger availability of uncertainty estimates. Limitations remain, for example, in how reanalyses represent global-scale changes to the water cycle. Regional reanalyses use high-resolution, limited-area models constrained by regional observations and with boundary conditions from global reanalyses. There is *high confidence* that regional reanalyses better represent the frequencies of extremes and variability in precipitation, surface air temperature and surface wind than global reanalyses and provide

ACCEPTED VERSION SUBJECT TO FINAL EDITING

estimates that are more consistent with independent observations than dynamical downscaling approaches. {1.5.2, 10.2.1.2, Annex I}

TS.1.2.2 Climate Model Performance

Developments in the latest generation CMIP6 climate and Earth system models, including new and better representation of physical, chemical and biological processes, as well as higher resolution, have improved the simulation of the recent mean climate of most large-scale indicators of climate change (*high confidence*, Figure TS.2) and many other aspects across the Earth system. Projections of the increase in global surface temperature, the pattern of warming, and global mean sea level rise from previous IPCC Assessment Reports and other studies are broadly consistent with subsequent observations, especially when accounting for the difference in radiative forcing scenarios used for making projections and the radiative forcings that actually occurred. While past warming is well simulated by the new generation of models, some individual models simulate past surface warming that is either below or above that observed. The information about how well models simulate past warming, as well as other insights from observations and theory, are used to assess projections of global warming. (see Cross-Section Box TS.1). Increasing horizontal resolution in global climate models improves the representation of small-scale features and the statistics of daily precipitation (*high confidence*). Earth system models, which include additional biogeochemical feedbacks, often perform as well as their lower-complexity global climate model counterparts, which do not account for these additional feedbacks (*medium confidence*). {1.3.6, 1.5.3, 3.1, 3.5.1, 3.8.2, 4.3.1, 4.3.4, 7.5, 8.5.1, 9.6.3.1}

Climate model simulations coordinated and collected as part of the World Climate Research Programme's Coupled Model Intercomparison Project Phase 6 (CMIP6), complemented by a range of results from the previous phase (CMIP5), constitute a key line of evidence supporting this Report. The latest generation of CMIP6 models have an improved representation of physical processes relative to previous generations, and a wider range of Earth system models now represent biogeochemical cycles. Higher-resolution models that better capture smaller-scale processes are also increasingly becoming available for climate change research (Figure TS.2, Panels a and b). Results from coordinated regional climate modelling initiatives, such as the Coordinated Regional Climate Downscaling Experiment (CORDEX) complement and add value to the CMIP global models, particularly in complex topography zones, coastal areas and small islands, as well as for extremes. {1.5.3, 1.5.4, 6.2.1.2, 6.3.6, 8.5.1, 10.3.3, Atlas.1.4}

Projections of the increase in global surface temperature and the pattern of warming from previous IPCC Assessment Reports and other studies are broadly consistent with subsequent observations (*limited evidence, high agreement*), especially when accounting for the difference in radiative forcing scenarios used for making projections and the radiative forcings that actually occurred. The AR5 and the SROCC projections of GMSL for the 2007–2018 period have been shown to be consistent with observed trends in GMSL and regional weighted mean tide gauges. {1.3.6, 9.6.3.1, Figure TS.3}

For most large-scale indicators of climate change, the simulated recent mean climate from CMIP6 models underpinning this assessment have improved compared to the CMIP5 models used in AR5 (*high confidence*). This is evident from the performance of 18 simulated atmospheric and land large-scale indicators of climate change between the three generations of models (CMIP3, CMIP5, and CMIP6) when benchmarked against reanalysis and observational data (Figure TS.2, Panel c). Earth system models, characterized by additional biogeochemical feedbacks, often perform at least as well as related, more constrained, lower-complexity models lacking these feedbacks (*medium confidence*). {3.8.2, 10.3.3.3}

The CMIP6 multi-model mean global surface temperature change from 1850–1900 to 2010–2019 is close to the best estimate of the observed warming. However, some CMIP6 models simulate a warming that is below or above the assessed *very likely* range. The CMIP6 models also reproduce surface temperature variations over the past millennium, including the cooling that follows periods of intense volcanism (*medium confidence*). For upper air temperature, an overestimation of the upper tropical troposphere warming by

ACCEPTED VERSION SUBJECT TO FINAL EDITING

about 0.1°C per decade between 1979 and 2014 persists in most CMIP5 and CMIP6 models (*medium confidence*), whereas the differences between simulated and improved satellite-derived estimates of change in global mean temperature through the depth of the stratosphere have decreased. {3.3.1}

Some CMIP6 models demonstrate an improvement in how clouds are represented. CMIP5 models commonly displayed a negative shortwave cloud radiative effect that was too weak in the present climate. These errors have been reduced, especially over the Southern Ocean, due to a more realistic simulation of supercooled liquid droplets with sufficient numbers and an associated increase in the cloud optical depth. Because a negative cloud optical depth feedback in response to surface warming results from 'brightening' of clouds via active phase change from ice to liquid cloud particles (increasing their shortwave cloud radiative effect), the extratropical cloud shortwave feedback in CMIP6 models tends to be less negative, leading to a better agreement with observational estimates (*medium confidence*). CMIP6 models generally represent more processes that drive aerosol–cloud interactions than the previous generation of climate models, but there is only *medium confidence* that those enhancements improve their fitness-for-purpose of simulating radiative forcing of aerosol–cloud interactions. {7.4.2, FAQ 7.2, 6.4}

CMIP6 models still have deficiencies in simulating precipitation patterns, particularly in the tropical ocean. Increasing horizontal resolution in global climate models improves the representation of small-scale features and the statistics of daily precipitation (*high confidence*). There is *high confidence* that high-resolution global, regional and hydrological models provide a better representation of land surfaces, including topography, vegetation and land-use change, which can improve the accuracy of simulations of regional changes in the terrestrial water cycle. {3.3.2, 8.5.1, 10.3.3, 11.2.3}

There is *high confidence* that climate models can reproduce the recent observed mean state and overall warming of temperature extremes globally and in most regions, although the magnitude of the trends may differ. There is *high confidence* in the ability of models to capture the large-scale spatial distribution of precipitation extremes over land. The overall performance of CMIP6 models in simulating the intensity and frequency of extreme precipitation is similar to that of CMIP5 models (*high confidence*). {Cross-Chapter Box 3.2, 11.3.3, 11.4.3}

The structure and magnitude of multi-model mean ocean temperature biases have not changed substantially between CMIP5 and CMIP6 (*medium confidence*). Since AR5, there is improved consistency between recent observed estimates and model simulations of changes in upper (<700 m) ocean heat content. The mean zonal and overturning circulations of the Southern Ocean and the mean overturning circulation of the North Atlantic (AMOC) are broadly reproduced by CMIP5 and CMIP6 models. {3.5.1, 3.5.4, 9.2.3, 9.3.2, 9.4.2}

CMIP6 models better simulate the sensitivity of Arctic sea ice area to anthropogenic CO_2 emissions, and thus better capture the time evolution of the satellite-observed Arctic sea ice loss (*high confidence*). The ability to model ice-sheet processes has improved substantially since AR5. As a consequence, we have *medium confidence* in the representation of key processes related to surface-mass balance and retreat of the grounding-line (the junction between a grounded ice sheet and an ice shelf, where the ice starts to float) in the absence of instabilities. However, there remains *low confidence* in simulations of ice-sheet instabilities, ice-shelf disintegration and basal melting owing to their high sensitivity to both uncertain oceanic forcing and uncertain boundary conditions and parameters. {1.5.3, 2.3.2, 3.4.1, 3.4.2, 3.8.2, 9.3.1, 9.3.2, 9.4.1, 9.4.2}

CMIP6 models are able to reproduce most aspects of the spatial structure and variance of the El Niño-Southern Oscillation (ENSO) and Indian Ocean Basin and Dipole modes of variability (*medium confidence*). However, despite a slight improvement in CMIP6, some underlying processes are still poorly represented. Models reproduce observed spatial features and variance of the Southern Annular Mode (SAM) and Northern Annular Modes (NAM) very well (*high confidence*). The summertime SAM trend is well captured, with CMIP6 models outperforming CMIP5 models (*medium confidence*). By contrast, the cause of the Northern Annular Mode (NAM) trend towards its positive phase is not well understood. In the Tropical Atlantic basin, which contains the Atlantic Zonal and Meridional modes, major biases in modelled mean state and variability remain. Model performance is limited in reproducing sea surface temperature anomalies for decadal modes of variability, despite improvements from CMIP5 to CMIP6 (*medium confidence*) (see

ACCEPTED VERSION SUBJECT TO FINAL EDITING

also TS.1.4.2.2, Table TS.4). {3.7.3-3.7.7}

Earth system models simulate globally averaged land carbon sinks within the range of observation-based estimates (*high confidence)*, but global-scale agreement masks large regional disagreements. There is also *high confidence* that the ESMs simulate the weakening of the global net flux of CO_2 into the ocean during the 1990s, as well as the strengthening of the flux from 2000. {3.6.1, 3.6.2}

Two important quantities used to estimate how the climate system responds to changes in GHG concentrations are the equilibrium climate sensitivity (ECS) and transient climate response (TCR[13]). The CMIP6 ensemble has broader ranges of ECS and TCR values than CMIP5 (see TS.3.2 for the assessed range). These higher sensitivity values can, in some models, be traced to changes in extratropical cloud feedbacks (*medium confidence*). To combine evidence from CMIP6 models and independent assessments of ECS and TCR, various emulators are used throughout the report. Emulators are a broad class of simple climate models or statistical methods that reproduce the behaviour of complex ESMs to represent key characteristics of the climate system, such as global surface temperature and sea level projections. The main application of emulators in AR6 is to extrapolate insights from ESMs and observational constraints to produce projections from a larger set of emissions scenarios, which is achieved due to their computational efficiency. These emulated projections are also used for scenario classification in WGIII. {Box 4.1, 4.3.4., 7.4.2, 7.5.6, CCB7.1, FAQ7.2}

[START FIGURE TS.2 HERE]

Figure TS.2: **Progress in climate models.** *The intent is to show present improvements in climate models in resolution, complexity and representation of key variables.* **(**a) Evolution of model horizontal resolution and vertical levels (based on Figure 1.19); (b) Evolution of inclusion of processes and resolution from CMIP Phase 3 (CMIP3) to CMIP6 (Annex II). (c) Centred pattern correlations between models and observations for the annual mean climatology over the period 1980–1999. Results are shown for individual CMIP3 (cyan), CMIP5 (blue) and CMIP6 (red) models (one ensemble member is used) as short lines, along with the corresponding ensemble averages (long lines). The correlations are shown between the models and the primary reference observational data set (from left to right: ERA5, GPCP-SG, CERES-EBAF, CERES-EBAF, CERES-EBAF, CERES-EBAF, JR-55, ERA5, ERA5, ERA5, ERA5, ERA5, ERA5, AIRS, ERA5, ESACCI-Soilmoisture, LAI3g, MTE). In addition, the correlation between the primary reference and additional observational data sets (from left to right: NCEP, GHCN, -, -, -, -, ERA5, HadISST, NCEP, NCEP, NCEP, NCEP, NCEP, NCEP, ERA5, NCEP, -, -, FLUXCOM) are shown (solid grey circles) if available. To ensure a fair comparison across a range of model resolutions, the pattern correlations are computed after regridding all datasets to a resolution of 4º in longitude and 5º in latitude. (Expanded from Figure 3.43; produced with ESMValTool version 2).

[END FIGURE TS.2 HERE]

TS.1.2.3 Understanding Climate Variability and Emerging Changes

Observed changes in climate are unequivocal at the global scale and are increasingly apparent on regional and local spatial scales. Both the rate of long-term change and the amplitude of year-to-year variations differ between regions and across climate variables, thus influencing when changes emerge or become apparent compared to natural variations (see Core Concepts Box). The signal of temperature change has emerged more clearly in tropical regions, where year-to-year variations tend to be small over land, than in regions with greater warming but larger year-to-year variations (*high confidence)* (Figure TS.3). Long-term changes in other variables have emerged in many regions, such as for some weather and climate extremes and Arctic sea ice area. {1.4.2, Cross-Chapter Box 3.1, 9.3.1, 11.3.2, 12.5.2}

[13] In this report, transient climate response is defined as the surface temperature response for the hypothetical scenario in which atmospheric carbon dioxide (CO_2) increases at 1% yr^{-1} from pre-industrial to the time of a doubling of atmospheric CO_2 concentration.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Observational datasets have been extended and improved since AR5, providing stronger evidence that the climate is changing and allowing better estimates of natural climate variability on decadal time scales. There is *very high confidence* that the slower rate of global surface temperature change observed over 1998–2012 compared to 1951–2012 was temporary, and was, with *high confidence*, induced by internal variability (particularly Pacific Decadal Variability) and variations in solar irradiance and volcanic forcing that partly offset the anthropogenic warming over this period. Global ocean heat content continued to increase throughout this period, indicating continuous warming of the entire climate system (*very high confidence*). Hot extremes also continued to increase during this period over land (*high confidence*). Even in a continually warming climate, periods of reduced and increased trends in global surface temperature at decadal time scales will continue to occur in the 21st century (*very high confidence*). {Cross-Chapter Box 3.1, 3.3.1, 3.5.1, 4.6.2, 11.3.2}

Since AR5, the increased use of 'large ensembles', or multiple simulations with the same climate model but using different initial conditions, supports improved understanding of the relative roles of internal variability and forced change in the climate system. Simulations and understanding of modes of climate variability, including teleconnections, have improved since AR5 (*medium confidence*), and larger ensembles allow a better quantification of uncertainty in projections due to internal climate variability. {1.4.2, 1.5.3, 1.5.4, 4.2, Box 4.1, 4.4.1, 8.5.2, 10.3.4, 10.4}

Changes in regional climate can be detected even though natural climate variations can temporarily increase or obscure anthropogenic climate change on decadal time scales. While anthropogenic forcing has contributed to multi-decadal mean precipitation changes in several regions, internal variability can delay emergence of the anthropogenic signal in long-term precipitation changes in many land regions (*high confidence*). {10.4.1, 10.4.2, 10.4.3}

Mean temperatures and heat extremes have emerged above natural variability in almost all land regions with *high confidence*. Changes in temperature-related variables, such as regional temperatures, growing season length, extreme heat and frost, have already occurred, and there is *medium confidence* that many of these changes are attributable to human activities. Several impact-relevant changes have not yet emerged from the natural variability but will emerge sooner or later in this century depending on the emissions scenario (*high confidence*). Ocean acidification and deoxygenation have already emerged over most of the global open ocean, as has a reduction in Arctic sea ice (*high confidence*). {9.3.1, 9.6.4, 11.2, 11.3, 12.4, 12.5, Atlas.3-Atlas.11}

[START FIGURE TS.3 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

TS.1.2.4 Understanding of Human Influence

The evidence for human influence on recent climate change has strengthened progressively from the IPCC Second Assessment Report to the AR5 and is even stronger in this assessment, including for regional scales and for extremes. Human influence in the IPCC context refers to the human activities that lead to or contribute to a climate response, such as the human-induced emissions of greenhouse gases that subsequently alter the atmosphere's radiative properties, resulting in warming of the climate system. Other human activities influencing climate include the emission of aerosols and other short-lived climate forcers, and land-use change such as urbanisation. Progress in our understanding of human influence is gained from longer observational datasets, improved paleoclimate information, a stronger warming signal since AR5, and improvements in climate models, physical understanding and attribution techniques (see Core Concepts Box). Since AR5, the attribution to human influence has become possible across a wider range of climate variables and climatic impact-drivers (CIDs, see Core Concepts Box). New techniques and analyses drawing on several lines of evidence have provided greater confidence in attributing changes in regional weather and climate extremes to human influence (*high confidence*). {1.3, 1.5.1, Appendix 1A, 3.1-3.8, 5.2, 6.4.2, 7.3.5, 7.4.4, 8.3.1, 10.4, Cross-Chapter Box 10.3, 11.2-11.9, 12.4, TS.3}

Combining the evidence from across the climate system increases the level of confidence in the attribution of observed climate change to human influence and reduces the uncertainties associated with assessments based on single variables.

Since AR5, the accumulation of energy in the Earth system has become established as a robust measure of the rate of global climate change on interannual-to-decadal time scales. The rate of accumulation of energy is equivalent to the Earth's energy imbalance and can be quantified by changes in the global energy inventory for all components of the climate system, including global ocean heat uptake, warming of the atmosphere, warming of the land, and melting of ice. Compared to changes in global surface temperature, the Earth's energy imbalance (see Core Concepts Box) exhibits less variability, enabling more accurate identification and estimation of trends.

Identifying the human-induced components contributing to the energy budget provides an implicit estimate of the human influence on global climate change. {Cross-Working Group Box: Attribution, 3.8, 7.2.2, Box 7.2 and Cross Chapter Box 9.1, TS.2, TS.3.1}

Regional climate changes can be moderated or amplified by regional forcing from land use and land-cover changes or from aerosol concentrations and other short-lived climate forcers (SLCFs). For example, the difference in observed warming trends between cities and their surroundings can partly be attributed to urbanization (*very high confidence*). While established attribution techniques provide confidence in our assessment of human influence on large-scale climate changes (as described in TS.2), new techniques developed since AR5, including attribution of individual events, have provided greater confidence in attributing changes in climate extremes to climate change. Multiple attribution approaches support the contribution of human influence to several regional multi-decadal mean precipitation changes (*high confidence*). Understanding about past and future changes in weather and climate extremes has increased due to better observation-based datasets, physical understanding of processes, an increasing proportion of scientific literature combining different lines of evidence, and improved accessibility to different types of climate models (*high confidence*) (see TS.2, TS.4). {Cross-Working Group Box: Attribution, 1.5, 3.2, 3.5, 5.2, 6.4.3, 8.3, 9.6, 10.1, 10.2, 10.3.3, 10.4.1, 10.4.2, 10.4.3, 10.5, 10.6, Cross-Chapter Box 10.3, Box 10.3, 11.1.6, 11.2-11.9, 12.4}.

TS.1.3 Assessing Future Climate Change

Various frameworks can be used to assess future climatic changes and to synthesize knowledge across climate change assessment in WGI, WGII and WGIII. These frameworks include: (i) scenarios, (ii) global warming levels and (iii) cumulative CO_2 emissions (see Core Concepts Box). The latter two offer scenario-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and path-independent approaches to assess future projections. Additional choices, for instance with regard to common reference periods and time windows for which changes are assessed, can further help to facilitate integration across the WGI report and across the whole AR6 (see TS.1.1). {1.4.1, 1.6, Cross-Chapter Box 1.4, 4.2.2, 4.2.4, Cross-Chapter Box 11.1}

TS.1.3.1 Climate Change Scenarios

A core set of five scenarios based on the Shared Socioeconomic Pathways (SSPs) are used consistently across this report: SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5. These scenarios cover a broader range of greenhouse gas and air pollutant futures than assessed in earlier WGI reports, and they include high-CO_2 emissions pathways without climate change mitigation as well as new low-CO_2 emissions pathways (Figure TS.4). In these scenarios, differences in air pollution control and variations in climate change mitigation stringency strongly affect anthropogenic emission trajectories of SLCFs. Modelling studies relying on the Representative Concentration Pathways (RCPs) used in the AR5 complement the assessment based on SSP scenarios, for example at the regional scale. A comparison of simulations from CMIP5 using the RCPs with SSP-based simulations from CMIP6 shows that about half of the increase in simulated warming in CMIP6 versus CMIP5 arises because higher climate sensitivity is more prevalent in CMIP6 model versions; the other half arises from higher radiative forcing in nominally corresponding scenarios (e.g., RCP8.5 and SSP5-8.5; *medium confidence*). The feasibility or likelihood of individual scenarios is not part of this assessment, which focuses on the climate response to a large range of emissions scenarios. {1.5.4, 1.6, Cross-Chapter Box 1.4, 4.2, 4.3, 4.6, 6.6, 6.7, Cross-Chapter Box 7.1, Atlas.2.1}

Climate change projections with climate models require information about future emissions or concentrations of greenhouse gases, aerosols, ozone depleting substances, and land use over time (Figure TS.4). This information can be provided by scenarios, which are internally consistent projections of these quantities based on assumptions of how socio-economic systems could evolve over the 21st century. Emissions from natural sources, such as the ocean and the land biosphere, are usually assumed to be constant, or to evolve in response to changes in anthropogenic forcings or to projected climate change. Natural forcings, such as past changes in solar irradiance and historical volcanic eruptions, are represented in model simulations covering the historical era. Future simulations assessed in this report account for projected changes in solar irradiance and for the long-term mean background forcing from volcanoes, but not for individual volcanic eruptions. Scenarios have a long history in IPCC as a method for systematically examining possible futures and allow to follow the cause-effect chain: from anthropogenic emissions, to changes in atmospheric concentrations, to changes in the Earth' energy balance ('forcing'), to changes in global climate and ultimately regional climate and climatic impact-drivers (Figure TS.4; see TS.2; Infographic TS.1). {1.5.4, 1.6.1, 4.2.2, 4.4.4, Cross-Chapter Box 4.1, 11.1}

[START FIGURE TS.4 HERE]

Figure TS.4: **The climate change cause-effect chain:** from anthropogenic emissions, to changes in atmospheric concentration, to changes in the Earth's energy balance ('forcing'), to changes to changes in global climate and ultimately regional climate and climatic impact-drivers. Shown is the core set of five SSP scenarios as well as emission and concentration ranges for the previous RCP scenarios in year 2100; CO_2 emissions ($GtCO_2\ yr^{-1}$), panel top left; CH_4 emissions (middle) and SO_2, NO_x emissions (all in $Mt\ yr^{-1}$), top right; concentrations of atmospheric CO_2 (ppm) and CH4 (ppb), second row left and right; effective radiative forcing for both anthropogenic and natural forcings ($W\ m^{-2}$), third row; changes in global surface air temperature (°C) relative to 1850–1900, fourth row; maps of projected temperature change (°C) (left) and changes in annual-mean precipitation (%) (right) at GWL 2°C relative to 1850–1900 (see also Figure TS.5), bottom row. Carbon cycle and non-CO_2 biogeochemical feedbacks will also influence the ultimate response to anthropogenic emissions (arrows on the left). {1.6.1, Cross-Chapter Box 1.4, 4.2.2, 4.3.1, 4.6.1, 4.6.2}

[END FIGURE TS.4 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The uncertainty in climate change projections that results from assessing alternative socio-economic futures, the so-called scenario uncertainty, is explored through the use of scenario sets. Designed to span a wide range of possible future conditions, these scenarios do not intend to match how events actually unfold in the future, and they do not account for impacts of climate change on the socio-economic pathways. Besides scenario uncertainty, climate change projections are also subject to climate response uncertainty (i.e., the uncertainty related to our understanding of the key physical processes and structural uncertainties in climate models) and irreducible and intrinsic uncertainties related to internal variability. Depending on the spatial and temporal scales of the projection, and on the variable of interest, the relative importance of these different uncertainties may vary substantially. {1.4.3, 1.6, 4.2.5, Box 4.1, 8.5.1}

In this report, a core set of five scenarios is used to explore climate change over the 21st century and beyond (Section TS.2). They are labelled SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5[14], and span a wide range of radiative forcing levels in 2100. Scenarios in AR6 cover a broader range of emissions futures than considered in AR5, including high CO_2 emissions scenarios without climate change mitigation as well as a low CO_2 emissions scenario reaching net zero CO_2 emissions (see Core Concepts Box) around mid-century. These SSP scenarios offer unprecedented detail of input data for ESM simulations and allow for a more comprehensive assessment of climate drivers and responses, in particular because some aspects, such as the temporal evolution of pollutants, emissions or changes in land use and land cover, span a broader range in the SSP scenarios than in the RCPs used in the AR5. Modelling studies utilizing the RCPs complement the assessment based on SSP scenarios, for example, at the regional scale (Section TS.4). Scenario extensions are based on assumptions about the post-2100 evolution of emissions or of radiative forcing that is independent from the modelling of socio-economic dynamics, which does not extend beyond 2100. To explore specific dimensions, such as air pollution or temporary overshoot of a given warming level, scenario variants are used in addition to the core set. {1.6.1, Cross-Chapter Box 1.4, 4.2.2, 4.2.6, 4.7.1, Cross-Chapter Box 7.1}

SSP1-1.9 represents the low end of future emissions pathways, leading to warming below 1.5°C in 2100 and limited temperature overshoot over the course of the 21st century (see Figure TS.6). At the opposite end of the range, SSP5-8.5 represents the very high warming end of future emissions pathways from the literature. SSP3-7.0 has overall lower GHG emissions than SSP5-8.5 but, for example, CO_2 emissions still almost double by 2100 compared to today's levels. SSP2-4.5 and SSP1-2.6 represent scenarios with stronger climate change mitigation and thus lower GHG emissions. SSP1-2.6 was designed to limit warming to below 2°C. Infographic TS.1 presents a narrative depiction of SSP-related climate futures. No likelihood is attached to the scenarios assessed in this report, and the feasibility of specific scenarios in relation to current trends is best informed by the WGIII contribution to AR6. In the scenario literature, the plausibility of some scenarios with high CO_2 emissions, such as RCP8.5 or SSP5-8.5, has been debated in light of recent developments in the energy sector. However, climate projections from these scenarios can still be valuable because the concentration-levels reached in RCP8.5 or SSP5-8.5 and corresponding simulated climate futures cannot be ruled out. That is because of uncertainty in carbon-cycle feedbacks which in nominally lower emissions trajectories can result in projected concentrations that are higher than the central concentration-levels typically used to drive model projections {1.6.1; Cross-Chapter Box 1.4; 4.2.2, 5.4; SROCC; Chapter 3 in WGIII}.

The socio-economic narratives underlying SSP-based scenarios differ in their assumed level of air pollution control. Together with variations in climate change mitigation stringency, this difference strongly affects anthropogenic emission trajectories of SLCFs, some of which are also air pollutants. SSP1 and SSP5 assume strong pollution control, projecting a decline of global emissions of ozone precursors (except methane) and of aerosols and most of their precursors in the mid- to long term. The reductions due to air pollution controls are further strengthened in scenarios that assume a marked decarbonization, such as SSP1-1.9 or SSP1-2.6. SSP2-4.5 is a medium pollution-control scenario with air pollutant emissions following current trends, and SSP3-7.0 is a weak pollution-control scenario with strong increases in emissions of air pollutants over the 21st century. Methane emissions in SSP-based scenarios vary with the overall climate change mitigation

[14] Throughout this report, scenarios are referred to as SSPx-y, where "SSPx" refers to the Shared Socioeconomic Pathway or "SSP" describing the socio-economic trends underlying the scenario and "y" refers to the approximate target level of radiative forcing (in W m^{-2}) resulting from the scenario in the year 2100.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

stringency, declining rapidly in SSP1-1.9 and SSP1-2.6 but declining only after 2070 in SSP5-8.5. SSP trajectories span a wider range of air pollutant emissions than considered in the RCP scenarios (see Figure TS.4), reflecting the potential for large regional differences in their assumed pollution policies. Their effects on climate and air pollution are assessed in Box TS.7. {4.4.4, 6.6.1, Figure 6.4; 6.7.1, Figure 6.19}

Since the RCPs are also labelled by the level of radiative forcing they reach in 2100, they can in principle be related to the core set of AR6 scenarios (Figure TS.4). However, the RCPs and SSP-based scenarios are not directly comparable. First, the gas-to-gas compositions differ; for example, the SSP5-8.5 scenario has higher CO_2 but lower methane concentrations compared to RCP8.5. Second, the projected 21st-century trajectories may differ, even if they result in the same radiative forcing by 2100. Third, the overall effective radiative forcing (see Core Concepts Box) may differ, and tends to be higher for the SSPs compared to RCPs that share the same nominal stratospheric-temperature-adjusted radiative forcing label. Comparing the differences between CMIP5 and CMIP6 projections (Cross-Section Box TS.1) that were driven by RCPs and SSP-based scenarios, respectively, indicates that about half of the difference in simulated warming arises because of higher climate sensitivity being more prevalent in CMIP6 model versions; the remainder arises from higher ERF in nominally corresponding scenarios (e.g., RCP8.5 and SSP5-8.5; *medium confidence*) (see TS.1.2.2). In SSP1-2.6 and SSP2-4.5, changes in effective radiative forcing also explain about half of the changes in the range of warming (*medium confidence*). For SSP5-8.5, higher climate sensitivity is the primary reason behind the upper end of the CMIP6-projected warming being higher than for RCP8.5 in CMIP5 (*medium confidence*). Note that AR6 uses multiple lines of evidence beyond CMIP6 results to assess global surface temperature under various scenarios (see Cross-Section Box TS.1 for the detailed assessment). {1.6, 4.2.2, 4.6.2.2, Cross-Chapter Box 7.1}

Earth system models can be driven by anthropogenic CO_2 emission ('emissions-driven' runs), in which case atmospheric CO_2 concentration is a projected variable; or by prescribed time-varying atmospheric concentrations ('concentration-driven' runs). In emissions-driven runs, changes in climate feed back on the carbon cycle and interactively modify the projected CO_2 concentration in each ESM, thus adding the uncertainty in the carbon cycle response to climate change to the projections. Concentration-driven simulations are based on a central estimate of carbon cycle feedbacks, while emissions-driven simulations help quantify the role of feedback uncertainty. The differences in the few ESMs for which both emission and concentration-driven runs were available for the same scenario are small and do not affect the assessment of global surface temperature projections discussed in Cross-Section Box TS.1 and Section TS.2 (*high confidence*). By the end of the 21st century, emission-driven simulations are on average around 0.1°C cooler than concentration-driven runs reflecting the generally lower CO_2 concentrations simulated by the emission driven ESMs, and a spread about 0.1°C greater reflecting the range of simulated CO_2 concentrations. However, these carbon cycle–climate feedbacks do affect the transient climate response to cumulative CO_2 emissions (TCRE[15]), and their quantification is crucial for the assessment of remaining carbon budgets consistent with global warming levels simulated by ESMs (see TS.3). {1.6.1, Cross-Chapter Box 1.4, 4.2, 4.3.1, 5.4.5, Cross-Chapter Box 7.1}

TS.1.3.2 Global Warming Levels and Cumulative CO_2 Emissions

Quantifying geographical response patterns of climate change at various global warming levels (GWLs), such as 1.5 or 2°C above the 1850–1900 period, is useful for characterizing changes in mean climate, extremes and climatic impact-drivers. GWLs are used in this report as a dimension of integration independent of the timing when the warming level is reached and of the emissions scenario that led to the warming. For many climate variables the response pattern for a given GWL is consistent across different scenarios. However, this is not the case for slowly responding processes, such as ice sheet and glacier mass loss, deep ocean warming, and the related sea level rise. The response of these variables depends on the time it takes to reach the GWL, differs if the warming is reached in a transient warming state or after a temporary overshoot of the warming level, and will continue to evolve, over centuries to millennia, even after global warming has stabilized. Different GWLs correspond closely to specific cumulative CO_2 emissions due to

[15] The transient surface temperature change per unit of cumulative CO_2 emissions, usually 1000 GtC;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

their near-linear relationship with global surface temperature. This report uses 1.0°C, 1.5°C, 2.0°C, 3.0°C, and 4.0°C above 1850–1900 conditions as a primary set of GWLs. {1.6.2, 4.2.4, 4.6.1, 5.5, Cross-Chapter Box 11.1, Cross-chapter Box 12.1}

For many indicators of climate change, such as seasonal and annual mean and extreme surface air temperatures and precipitation, the geographical patterns of changes are well estimated by the level of global surface warming, independently of the details of the emission pathways that caused the warming, or the time at which the level of warming is attained. GWLs, defined as a global surface temperature increase of, for example, 1.5°C or 2°C relative to the mean of 1850–1900, are therefore a useful way to integrate climate information independently of specific scenarios or time periods. {1.6.2, 4.2.4, 4.6.1, 11.2.4, Cross-Chapter Box 11.1}

The use of GWLs allows disentangling the contribution of changes in global warming from regional aspects of the climate response, as scenario differences in response patterns at a given GWL are often smaller than model uncertainty and internal variability. The relationship between the GWL and response patterns is often linear, but integration of information can also be done for non-linear changes, like the frequency of heat extremes. The requirement is that the relationship to the GWL is broadly independent of the scenario and relative contribution of radiative forcing agents. {1.6, 11.2.4, Cross-Chapter Box 11.1}

The GWL approach to integration of climate information also has some limitations. Variables that are quick to respond to warming, like temperature and precipitation, including extremes, sea ice area, permafrost and snow cover, show little scenario dependence for a given GWL, whereas slow-responding variables such as glacier and ice sheet mass, warming of the deep ocean and their contributions to sea level rise, have substantial dependency on the trajectory of warming taken to reach the GWL. A given GWL can also be reached for different balances between anthropogenic forcing agents, such as long-lived greenhouse gas and SLCF emissions, and the response patterns may depend on this balance. Finally, there is a difference in the response even for temperature-related variables if a GWL is reached in a rapidly warming transient state or in an equilibrium state when the land–sea warming contrast is less pronounced. In this Report the climate responses at different GWLs are calculated based on climate model projections for the 21st century (see Figure TS.5), which are mostly not in equilibrium. The SSP1-1.9 scenario allows assessing the response to a GWL of about 1.5°C after a (relatively) short-term stabilization by the end of the 21st century. {4.6.2, 9.3.1.1, 9.5.2.3, 9.5.3.3, 11.2.4, Cross-Chapter Box 11.1, Cross-chapter Box 12.1}

Global warming levels are highly relevant as a dimension of integration across scientific disciplines and socio-economic actors and are motivated by the long-term goal in the Paris Agreement of ‘holding the increase in the global average temperature to well below 2°C above pre-industrial levels and to pursue efforts to limit the temperature increase to 1.5°C above pre-industrial levels’. The evolution of aggregated impacts with temperature levels has also been widely used and embedded in the WGII assessment. This includes the ‘Reasons for Concern’ (RFC) and other ‘burning ember’ diagrams in IPCC WGII. The RFC framework has been further expanded in the SR1.5, the SROCC and SRCCL by explicitly looking at the differential impacts between half-degree GWLs and the evolution of risk for different socio-economic assumptions. {1.4.4, 1.6.2, 11.2.4, 12.5.2, Cross-chapter Box 11.1, Cross-Chapter Box 12.1}

SR1.5 concluded, ‘climate models project robust differences in regional climate characteristics between present-day and global warming of 1.5°C, and between 1.5°C and 2°C’. This report adopts a set of common GWLs across which climate projections, impacts, adaptation challenges and climate change mitigation challenges can be integrated, within and across the three WGs, relative to 1850–1900. The core set of GWLs in this Report are 1.0°C (close to present day conditions), 1.5°C, 2.0°C, 3.0°C, and 4.0°C. {1.4, 1.6.2, Cross-Chapter Box 1.2, Table 1.5, Cross-chapter Box 11.1}

Connecting Scenarios and Global Warming Levels

In this report, scenario-based climate projections are translated into GWLs by aggregating the ESM model response at specific GWL across scenarios (see Figure TS.5 and Figure TS.6). The climate response pattern for the 20-year period around when individual simulations reach a given GWL are averaged across all

ACCEPTED VERSION SUBJECT TO FINAL EDITING

models and scenarios that reach that GWL. The best estimate and *likely* range of the timing of when a certain GWL is reached under a particular scenario (or 'GWL-crossing time'), however, is based not only on CMIP6 output, but on a combined assessment taking into account the observed warming to date, CMIP6 output and additional lines of evidence (see Cross-Section Box TS.1). {4.3.4, Cross-Chapter Box 11.1, Atlas.2, Interactive Atlas}

[START FIGURE TS.5 HERE]

Figure TS.5: How scenarios are linked to global warming levels (GWLs), and examples of the evolution of patterns of change with global warming levels. Left: Illustrative example of GWLs defined as global surface temperature response to anthropogenic emissions in unconstrained CMIP6 simulations, for two illustrative scenarios (SSP1-2.6 and SSP3-7.0). The time when a given simulation reaches a GWL, e.g., +2°C, relative to 1850-1900 is taken as the time when the central year of a 20-year running mean first reaches that level of warming. See the dots for +2°C, and how not all simulations reach all levels of warming. The assessment of the timing when a GWL is reached takes into account additional lines of evidence and is discussed in Cross-Section Box TS.1. Right: Multi-model, multi-simulation average response patterns of change in near-surface air temperature, precipitation (expressed as percentage change) and soil moisture (expressed in standard deviations of interannual variability), for three GWLs. The number to the top right of the panels shows the number of model simulations averaged across including all models that reach the corresponding GWL in any of the 5 SSPs. See TS.2 for discussion. (See also Cross-Chapter Box 11.1)

[END FIGURE TS.5 HERE]

Global warming levels are closely related to cumulative CO_2 (and in some cases CO_2-equivalent) emissions. This report confirms the assessment of the WGI AR5 and SR1.5 that a near-linear relationship exists between cumulative CO_2 emissions and the resulting increase in global surface temperature (Section TS.3.2). This implies that continued CO_2 emissions will cause further warming and associated changes in all components of the climate system. For declining cumulative CO_2 emissions (i.e., if negative net emissions are achieved), the relationship is less strong for some components, such as the hydrological cycle. The WGI report uses cumulative CO_2 emissions to compare climate response across scenarios and provides a link to the emission pathways assessment in WGIII. The advantage of using cumulative CO_2 emissions is that it is an inherent emissions scenario characteristic rather than an outcome of the scenario-based projections, where uncertainties in the cause–effect chain from emissions to temperature change are important (Figure TS.4), for example, the uncertainty in effective radiative forcing (ERF) and transient climate response (TCR). Cumulative CO_2 emissions can also provide a link to the assessments of mitigation options. Cumulative CO_2 emissions do not carry information about non-CO_2 emissions, although these can be included with specific emission metrics to estimate CO_2-equivalent emissions. (TS.3.3) {1.3.2, 1.6, 4.6.2, 5.5, 7.6, 8.4.3}

TS.1.4 From Global to Regional Climate Information for Impact and Risk Assessment

The WGI AR6 has an expanded focus on regional information supported by the increased availability of coordinated regional climate model ensemble projections and improvements in the sophistication and resolution of global and regional climate models (*high confidence*). Multiple lines of evidence can be used to construct climate information on a global to regional scale and can be further distilled in a co-production process to meet user needs (*high confidence*). To better support risk assessment, a common risk framework across all three Working Groups has been implemented in AR6, and low-likelihood but high-impact outcomes are explicitly addressed in WGI by using physical climate storylines (see Core Concepts Box). Climatic impact-drivers are physical climate system conditions (e.g., means, events, extremes) that affect an element of society or ecosystems. They are the WGI contribution to the risk framing without anticipating whether their impact provides potential opportunities or is detrimental (i.e., as for hazards). Many global and regional climatic impact-drivers have a direct relation to global warming levels (*high confidence*). {1.4.4, 1.5.2-1.5.4, 4.8, 10.1, 10.5.1, **11.2.4, 11.9,** 12.1-12.3, 12.6, Atlas.1.3.3-1.3.4, Atlas.1.4, Atlas.1.4.4, Boxes

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.2 and 11.2, Cross-Chapter Boxes 1.3, 10.3, 11.1, 12.1 and 12.2}

Climate change is a global phenomenon, but manifests differently in different regions. The impacts of climate change are generally experienced at local, national and regional scales, and these are also the scales at which decisions are typically made. Robust climate change information is increasingly available at regional scales for impact and risk assessments. Depending on the climate information context, geographical regions in AR6 may refer to larger areas, such as sub-continents and oceanic regions, or to typological regions, such as monsoon regions, coastlines, mountain ranges or cities, as used in TS.4. A new set of standard AR6 WGI reference regions has also been included in this report (Fig. TS.6 bottom panels). {1.4.5, 10.1, 11.9, 12.1-12.4, Atlas.1.3.3-1.3.4}

Global and regional climate models are important sources of climate information at the regional scale. Since AR5, a more comprehensive assessment of past and future evolution of a range of climate variables on a regional scale has been enabled by the increased availability of coordinated ensemble regional climate model projections and improvements in the level of sophistication and resolution of global and regional climate models. This has been complemented by observational, attribution and sectoral-vulnerability studies informing, for instance, about impact-relevant tolerance thresholds. {10.3.3, 11.9, 12.1, 12.3, 12.6, Atlas.3-Atlas.11, Interactive Atlas}

Multiple lines of evidence derived from observations, model simulations and other approaches can be used to construct climate information on a regional scale as described in detail in TS.4.1.1 and TS.4.1.2. Depending on the phenomena and specific context, these sources and methodologies include theoretical understanding of the relevant processes, drivers and feedbacks of climate at regional scale, trends in observed data from multiple datasets, and the attribution of these trends to specific drivers. Furthermore, simulations from different model types (including global and regional climate models, emulators, statistical downscaling methods, etc.) and experiments (e.g., CMIP, CORDEX, and large ensembles of single-model simulations with different initial conditions), attribution methodologies as well as other relevant local knowledge (e.g., indigenous knowledge) are utilized. (see Box TS.11). {1.5.3,1.5.4, Cross-Chapter Box 7.1, 10.2,10.3-10.6, 11.2, Atlas.1.4, Cross-Chapter Box 10.3}

From the multiple lines of evidence, climate information can be distilled in a co-production process that involves users, related stakeholders and producers of climate information, considering the specific context of the question at stake, the underlying values, and the challenge of communicating across different communities. The co-production process is an essential part of climate services, which are discussed in TS.4.1.2. {10.5, 12.6, Cross-Chapter Box 12.2}

[START FIGURE TS.6 HERE]

Figure TS.6: **A graphical abstract for key aspects of the Technical Summary related to observed and projected changes in global surface temperature and associated regional changes in climatic impact-drivers relevant for impact and risk assessment.** Top left: a schematic representation of the likelihood for equilibrium climate sensitivity (ECS), consistent with the AR6 assessment (see Chapter 7; TS.3). ECS values above 5°C and below 2°C are termed low-likelihood high warming (LLHW) and low-likelihood low warming, respectively. Top right: Observed (see Cross-Section Box TS.1) and projected global surface temperature changes, shown as global warming levels (GWL) relative to 1850-1900, using the assessed 95% (top), 50% (middle) and 5% (bottom) likelihood time series (see Chapter 4; TS.2). Bottom panels show maps of CMIP6 median projections of two climatic impact-drivers (CIDs) at three different GWLs (columns for 1.5, 2 and 4°C) for the AR6 land regions (see Chapters 1, 10, Atlas; TS.4). The heat warning index is the number of days per year averaged across each region at which a heat warning for human health at level 'danger' would be issued according to the U.S. National Oceanic and Atmospheric Administration (NOAA) (NOAA HI41, see Chapter 12 and Technical Annex VI). The maps of extreme rainfall changes show the percentage change in the amount of rain falling on the wettest day of a year (Rx1day, relative to 1995-2014, see Chapter 11) averaged across each region when the respective GWL is reached. Additional CIDs are discussed in TS.4.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END FIGURE TS.6 HERE]

With the aim of informing decision-making at local or regional scales, a common risk framework has been implemented in AR6. Methodologies have been developed to construct more impact- and risk-relevant climate change information tailored to regions and stakeholders. Physical storyline approaches are used in order to build climate information based on multiple lines of evidence, and which can explicitly address physically plausible, but low-likelihood, high-impact outcomes and uncertainties related to climate variability for consideration in risk assessments (see Figure TS.6). {4.8, 12.1-12.3, 12.6, Box 9.4, 10.5, Box 10.2, Box 11.2, Cross-Chapter Box 1.3, Glossary}

The climatic impact-driver framework developed in AR6 supports an assessment of changing climate conditions that are relevant for sectoral impacts and risk assessment. Climatic impact-drivers (CIDs) are physical climate system conditions (e.g., means, extremes, events) that affect an element of society or ecosystems and are thus a potential priority for providing climate information. For instance, the heat index used by the U.S. National Oceanic and Atmospheric Administration (NOAA HI) for issuing heat warnings is a CID index that can be associated with adverse human health impacts due to heat stress (see Figure TS.6). Depending on system tolerance, CIDs and their changes can be detrimental (i.e., hazards in the risk framing), beneficial, neutral, or a mixture of each across interacting system elements, regions and sectors (aligning with WGII Sectoral Chapters 2–8). Each sector is affected by multiple CIDs, and each CID affects multiple sectors. Climate change has already altered CID profiles and resulted in shifting magnitude, frequency, duration, seasonality and spatial extent of associated indices (*high confidence*) (see regional details in TS.4.3). {12.1-12.4, Table 12.1, Table 12.2, Technical Annex VI}

Many global- and regional-scale CIDs, including extremes, have a direct relation to global warming levels (GWLs) and can thus inform the hazard component of 'Representative Key Risks' and 'Reasons for Concern' assessed by AR6 WGII. These include heat, cold, wet and dry hazards, both mean and extremes; cryospheric hazards (snow cover, ice extent, permafrost) and oceanic hazards (marine heatwaves) (*high confidence*) (Figure TS.6). Establishing links between specific GWLs with tipping points and irreversible behaviour is challenging due to model uncertainties and lack of observations, but their occurrence cannot be excluded, and their likelihood of occurrence generally increases at greater warming levels (Box TS.1, TS.9). {11.2.4, Box 11.2, Cross-Chapter Boxes 11.1 and 12.1}

[START CROSS-SECTION BOX TS.1 HERE]

Cross-Section Box TS.1: Global Surface Temperature Change

This box synthesizes the outcomes of the assessment of past, current and future global surface temperature. Global mean surface temperature (GMST) and global surface air temperature (GSAT) are the two primary metrics of global surface temperature used to estimate global warming in IPCC reports. GMST merges sea surface temperatures (SSTs) over the ocean and 2 m air temperature over land and sea ice areas and is used in most paleo, historical and present-day observational estimates. The GSAT metric is 2 m air temperature over all surfaces and is the diagnostic generally used from climate models. Changes in GMST and GSAT over time differ by at most 10% in either direction (*high confidence*), but conflicting lines of evidence from models and direct observations, combined with limitations in theoretical understanding, lead to *low confidence* in the sign of any difference in long-term trend. Therefore, long-term changes in GMST/GSAT are presently assessed to be identical, with expanded uncertainty in GSAT estimates. Hence the term global surface temperature is used in reference to both quantities in the text of the TS and SPM. {Cross-Chapter Box 2.3}

Global surface temperature has increased by 1.09 [0.95 to 1.20] °C from 1850–1900 to 2011–2020, and the last decade was *more likely than not* warmer than any multi-centennial period after the Last Interglacial, roughly 125,000 years ago. The *likely* range of human-induced warming in global surface temperature in 2010–2019 relative to 1850–1900 is 1.07 [0.8 to 1.3] °C, encompassing the observed warming, while the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

change attributable to natural forcing is only –0.1°C to +0.1°C. Compared to 1850–1900, average global surface temperature over the period 2081–2100 is *very likely* to be higher by 1.0°C–1.8°C in the low CO_2 emissions scenario SSP1-1.9 and by 3.3°C–5.7°C in the high CO_2 emissions scenario SSP5-8.5. In all scenarios assessed here except SSP5-8.5, the central estimate of 20-year averaged global surface warming crossing the 1.5°C level lies in the early 2030s, which is about ten years earlier than the midpoint of the *likely* range (2030–2052) assessed in the SR1.5. It is *more likely than not* that under SSP1-1.9, global surface temperature relative to 1850–1900 will remain below 1.6°C throughout the 21st century, implying a potential temporary overshoot of 1.5°C global warming of no more than 0.1°C. Global surface temperature in any individual year, could exceed 1.5°C relative to 1850–1900 by 2030 with a likelihood between 40% and 60% across the scenarios considered here (*medium confidence*). A 2°C increase in global surface temperature relative to 1850–1900 will be crossed under SSP5-8.5 but is *extremely unlikely* to be crossed under SSP1-1.9. Periods of reduced and increased GSAT trends at decadal time scales will continue to occur in the 21st century (*very high confidence*). The effect of strong mitigation on 20-year global surface temperature trends would be *likely* to emerge during the near term (2021–2040), assuming no major volcanic eruptions occur. (Figure TS.8; Cross-Section Box TS.1, Figure 1), {2.3, 3.3, 4.3, 4.4, 4.6, 7.3}.

Surface Temperature History

Dataset innovations, particularly more comprehensive representation of polar regions, and the availability of new datasets have led to an assessment of increased global surface temperature change relative to the directly equivalent estimates reported in AR5. The contribution of changes in observational understanding alone between AR5 and AR6 in assessing temperature changes from 1850–1900 to 1986–2005 is estimated at 0.08 [–0.01 to 0.12] °C. From 1850–1900 to 1995–2014, global surface temperature increased by 0.85 [0.69 to 0.95] °C, and to the most recent decade (2011–2020) by 1.09 [0.95 to 1.20] °C. Each of the last four decades has in turn been warmer than any decade that preceded it since 1850. Temperatures have increased faster over land than over the ocean since 1850–1900, with warming to 2011–2020 of 1.59 [1.34 to 1.83] °C over land and 0.88 [0.68 to 1.01] °C over the ocean. {2.3.1, Cross-Chapter Box 2.3}

Global surface temperature during the period 1850–1900 is used as an approximation for pre-industrial conditions for consistency with AR5 and AR6 Special Reports, whilst recognizing that radiative forcings have a baseline of 1750 for the start of anthropogenic influences. It is *likely* that there was a net anthropogenic forcing of 0.0–0.3 Wm^{-2} in 1850–1900 relative to 1750 (*medium confidence*), and from the period around 1750 to 1850–1900 there was a change in global surface temperature of around 0.1°C (*likely* range –0.1 to +0.3°C, *medium confidence*), with an anthropogenic component of 0.0°C–0.2°C (*likely* range, *medium confidence*). {Cross-Chapter Box 1.2, 7.3.5}.

Global surface temperature has evolved over geological time (Figure TS.1, Box TS.2). Beginning approximately 6500 years ago, global surface temperature generally decreased, culminating in the coldest multi-century interval of the post-glacial period (since roughly 7000 years ago), which occurred between around 1450 and 1850 (*high confidence*). Over the last 50 years, global surface temperature has increased at an observed rate unprecedented in at least the last two thousand years (*medium confidence*), and it is *more likely than not* that no multi-centennial period after the Last Interglacial (roughly 125,000 years ago) was warmer globally than the most recent decade (Cross-Section Box TS.1, Figure 1). During the mid-Pliocene Warm Period, around 3.3–3.0 million years ago, global surface temperature was 2.5°C–4°C warmer, and during the Last Interglacial, it was 0.5°C–1.5°C warmer than 1850–1900 (*medium confidence*). {2.3.1, Cross-Chapter Box 2.1 and 2.4}

[START CROSS-SECTION BOX TS.1, FIGURE 1 HERE]

Cross-Section Box TS.1, Figure 1: Earth's surface temperature history and future with key findings annotated within each panel. *The intent of this figure is to show global surface temperature observed changes from the Holocene to now, and projected changes.* (a) Global surface temperature over the Holocene divided into three time scales. (i) 12,000 to 1000 years ago (10,000 BCE to 1000 CE) in 100-year time steps, (ii) 1000 to 1900

ACCEPTED VERSION SUBJECT TO FINAL EDITING

CE, 10-year smooth, and (iii) 1900 to 2020 CE (mean of four datasets in panel (c)). Median of the multi-method reconstruction (bold lines), with 5% and 95% percentiles of the ensemble members (thin lines). Vertical bars are 5th to 95th percentile ranges of estimated global surface temperature for the Last Interglacial and mid Holocene (*medium confidence*) (Section 2.3.1.1). All temperatures relative to 1850–1900. (b) Spatially resolved trends (°C per decade) for (upper map) HadCRUTv5 over 1981–2020, and (lower map, total change) multi-model mean projected changes from 1995–2014 to 2081–2010 in the SST3-7.0 scenario. Observed trends have been calculated where data are present in both the first and last decade and for at least 70% of all years within the period using OLS. Significance is assessed with AR(1) correction and denoted by stippling. Hatched areas in the lower map show areas of conflicting model evidence on significance of changes. (c) Temperature from instrumental data for 1850–2020, including annually resolved averages for the four global surface temperature datasets assessed in Section 2.3.1.1.3 (see text for references). The grey shading shows the uncertainty associated with the HadCRUTv5 estimate. All temperatures relative to the 1850–1900 reference period. (d) Recent past and 2015–2050 evolution of annual mean global surface temperature change relative to 1850–1900, from HadCRUTv5 (black), CMIP6 historical simulations (up to 2014, in grey, ensemble mean solid, 5% and 95% percentiles dashed, individual models thin), and CMIP6 projections under scenario SSP2-4.5, from four models that have an equilibrium climate sensitivity near the assessed central value (thick yellow). Solid thin coloured lines show the assessed central estimate of 20-year change in global surface temperature for 2015–2050 under three scenarios, and dashed thin coloured lines the corresponding 5% and 95% quantiles. (e) Assessed projected change in 20-year running mean global surface temperature for five scenarios (central estimate solid, *very likely* range shaded for SSP1-2.6 and SSP3-7.0), relative to 1995–2014 (left y-axis) and 1850–1900 (right y-axis). The y-axis on the right-hand side is shifted upward by 0.85°C, the central estimate of the observed warming for 1995–2014, relative to 1850–1900. The right y-axis in (e) is the same as the y-axis in (d).

[END CROSS-SECTION BOX TS.1, FIGURE 1 HERE]

Current Warming

There is *very high confidence* that the CMIP6 model ensemble reproduces observed global surface temperature trends and variability since 1850 with errors small enough for detection and attribution of human-induced warming. The CMIP6 multi-model mean global surface warming between 1850–1900 and 2010–2019 is close to the best estimate of observed warming, though some CMIP6 models simulate a warming that is outside the assessed *very likely* observed range. {3.3.1}

The *likely* range of human-induced change in global surface temperature in 2010–2019[16] relative to 1850–1900 is 1.07 [0.8 to 1.3] °C (Figure Cross-Section Box TS.1, Figure 1), encompassing the observed warming for that period of 1.06 [0.88 to 1.21] °C, while change attributable to natural forcing is only –0.1 to +0.1°C. This assessment is consistent with an estimate of the human-induced global surface temperature rise based on assessed ranges of perturbations to the top of the atmosphere (effective radiative forcing), and metrics of feedbacks of the climate response (equilibrium climate sensitivity and the transient climate response). Over the same period, well-mixed greenhouse gas forcing *likely* warmed global surface temperature by 1.0°C to 2.0°C, while aerosols and other anthropogenic forcings *likely* cooled global surface temperature by 0.0°C to 0.8°C. {2.3.1, 3.3.1, 7.3.5, Cross-Chapter Box 7.1}

The observed slower global surface temperature increase (relative to preceding and following periods) in the 1998–2012 period, sometimes referred to as 'the hiatus', was temporary (*very high confidence*). The increase

[16] Assessment of human-induced warming took place before 2020 data were available and hence concludes in 2019.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in global surface temperature during the 1998–2012 period is also greater in the data sets used in the AR6 assessment than in those available at the time of AR5. Using these updated observational data sets and a like-for-like consistent comparison of simulated and observed global surface temperature, all observed estimates of the 1998–2012 trend lie within the *very likely* range of CMIP6 trends. Since 2012, global surface temperature has warmed strongly, with the past five years (2016–2020) being the hottest five-year period between 1850 and 2020 (*high confidence*). {2.3.1, 3.3.1, 3.5.1, Cross-Chapter Box 3.1}

Future Changes in Global Surface Temperature

The AR6 assessment of future change in global surface temperature is, for the first time in an IPCC report, explicitly constructed by combining new projections for the SSP scenarios with observational constraints based on past simulated warming as well as the AR6-updated assessment of equilibrium climate sensitivity and transient climate response. Climate forecasts initialized from the observed climate state have in addition been used for the period 2019–2028. The inclusion of additional lines of evidence has reduced the assessed uncertainty ranges for each scenario (Cross-Section Box TS.1, Figure 1). {4.3.1, 4.3.4, Box 4.1, 7.5}

During the near term (2021–2040), a 1.5°C increase in global surface temperature, relative to 1850–1900, is *very likely* to occur in scenario SSP5-8.5, *likely* to occur in scenarios SSP2-4.5 and SSP3-7.0, and *more likely than not* to occur in scenarios SSP1-1.9 and SSP1-2.6. The time of crossing a warming level here is defined here as the midpoint of the first 20-year period during which the average global surface temperature exceeds the level. In all scenarios assessed here except SSP5-8.5, the central estimate of crossing the 1.5°C level lies in the early 2030s. This is about ten years earlier than the midpoint of the *likely* range (2030–2052) assessed in the SR1.5, which assumed continuation of the then-current warming rate; this rate has been confirmed in the AR6. Roughly half of the ten-year difference arises from a larger historical warming diagnosed in AR6. The other half arises because for central estimates of climate sensitivity, most scenarios show stronger warming over the near term than was estimated as 'current' in SR1.5 (*medium confidence*). (Cross-Section Box TS.1, Table 1) {2.3.1, Cross-Chapter Box 2.3, 3.3.1, 4.3.4, BOX 4.1}

It is *more likely than not* that under SSP1-1.9, global surface temperature relative to 1850–1900 will remain below 1.6°C throughout the 21st century, implying a potential temporary overshoot of 1.5°C global warming of no more than 0.1°C. If climate sensitivity lies near the lower end of the assessed *very likely* range, crossing the 1.5°C warming level is avoided in scenarios SSP1-1.9 and SSP1-2.6 (*medium confidence*). Global surface temperature in any individual year, in contrast to the 20-year average, could by 2030 exceed 1.5°C relative to 1850–1900 with a likelihood between 40% and 60%, across the scenarios considered here (*medium confidence*). (Cross-Section Box TS.1, Table 1) {4.3.4, 4.4.1, BOX 4.1, 7.5}

During the 21st century, a 2°C increase in global surface temperature relative to 1850–1900 will be crossed under SSP5-8.5 and SSP3-7.0, will *extremely likely* be crossed under SSP2-4.5, but is *unlikely* to be crossed under SSP1-2.6 and *extremely unlikely* to be crossed under SSP1-1.9. For the mid-term period 2041–2060, this 2°C global warming level is *very likely* to be crossed under SSP5-8.5, *likely* to be crossed under SSP3-7.0, and *more likely than not* to be crossed under SSP2-4.5. (Cross-Section Box TS.1, Table 1) {4.3.4}

Events of reduced and increased global surface temperature trends at decadal timescales will continue to occur in the 21st century, but will not affect the centennial warming (*very high confidence*). If strong mitigation is applied from 2020 onward as reflected in SSP1-1.9, its effect on 20-year trends in global surface temperature would *likely* emerge during the near term (2021–2040), measured against an assumed non-mitigation scenario such as SSP3-7.0 and SSP5-8.5. All statements about crossing the 1.5°C level assume that no major volcanic eruption occurs during the near term (Cross-Section Box TS.1, Table 1). {2.3.1, Cross-chapter Box 2.3, 4.3.4, 4.4.1, 4.6.3, Box 4.1}

Compared to 1850–1900, average global surface temperature over the period 2081–2100 is *very likely* to be higher by 1.0°C–1.8°C in the low CO_2 emissions scenario SSP1-1.9 and by 3.3°C–5.7°C in the high CO_2 emissions scenario SSP5-8.5. For the scenarios SSP1-2.6, SSP2-4.5, and SSP3-7.0, the corresponding *very likely* ranges are 1.3°C–2.4°C, 2.1°C–3.5°C, and 2.8°C–4.6°C, respectively. The uncertainty ranges for the period 2081–2100 continue to be dominated by the uncertainty in equilibrium climate sensitivity and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

transient climate response (*very high confidence*) (Cross-Section Box TS.1, Table 1). {4.3.1, 4.3.4, 4.4.1, 7.5}

The CMIP6 models project a wider range of global surface temperature change than the assessed range (*high confidence*); furthermore, the CMIP6 global surface temperature increase tends to be larger than in CMIP5 (*very high confidence*). {4.3.1, 4.3.4, 4.6.2, 7.5.6}

[START CROSS-SECTION BOX TS.1, TABLE 1 HERE]

Cross-Section Box TS.1, Table 1: Assessment results for 20-year averaged change in global surface temperature based on multiple lines of evidence. The change is displayed in °C relative to the 1850–1900 reference period for selected time periods, and as the first 20-year period during which the average global surface temperature change exceeds the specified level relative to the period 1850–1900. The entries give both the central estimate and, in parentheses, the *very likely* (5–95%) range. An entry n.c. means that the global warming level is not crossed during the period 2021–2100.

[END CROSS-SECTION BOX TS.1 HERE]

TS.2 Large-scale Climate Change: Mean Climate, Variability and Extremes

This section summarizes knowledge about observed and projected large-scale climate change (including variability and extremes), drivers and attribution of observed changes to human activities. It describes observed and projected large-scale changes associated with major components of the climate system: atmosphere, ocean (including sea level change), land, biosphere and cryosphere, and the carbon, energy and water cycles. In each subsection, reconstructed past, observed and attributed recent, and projected near- and long-term changes to mean climate, variability and extremes are presented, where possible, in an integrated way. See TS.1.3.1 for information on the scenarios used for projections.

TS.2.1 Changes Across the Global Climate System

In addition to global surface temperature (Cross-Section Box TS.1), a wide range of indicators across all components of the climate system is changing rapidly (Figure TS.7), with many at levels unseen in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

millennia. The observed changes provide a coherent picture of a warming world, many aspects of which have now been formally attributed to human influences, and human influence on the climate system as a whole is assessed as unequivocal for the first time in IPCC assessment reports (Table TS.1, Figure TS.7). It is *virtually certain* that global surface temperature rise and associated changes can be limited through rapid and substantial reductions in global GHG emissions. Continued GHG emissions greatly increase the likelihood of potentially irreversible changes in the global climate system (Box TS.3), in particular with respect to the contribution of ice sheets to global sea level change (*high confidence*). {2.3, 3.8, 4.3, 4.6, 4.7, 7.2-7.4, 9.2-9.6, CCB 7.1}

Earth system model (ESM) simulations of the historical period since 1850 are only able to reproduce the observed changes in key climate indicators when anthropogenic forcings are included (Figure TS.7). Taken together with numerous formal attribution studies across an even broader range of indicators and theoretical understanding, this underpins the unequivocal attribution of observed warming of the climate system to human influence (Table TS.1). {2.3, 3.8}

[START FIGURE TS.7 HERE]

Figure TS.7: **Simulated and observed changes compared to the 1995–2014 average in key large-scale indicators of climate change across the climate system, for continents, ocean basins and globally up to 2014.** Black lines show observations, orange lines and shading show the multi-model mean and 5–95th percentile ranges for CMIP6 historical simulations including anthropogenic and natural forcing, and green lines and shading show corresponding ensemble means and 5-95th percentile ranges for CMIP6 natural-only simulations. Observations after 2014 (including, for example, a strong subsequent decrease of Antarctic sea-ice area that leads to no significant overall trend since 1979) are not shown because the CMIP6 historical simulations end in 2014. A 3-year running mean smoothing has been applied to all observational time series. {3.8, Figure 3.41}

[END FIGURE TS.7 HERE]

[START TABLE TS.1 HERE]

Table TS.1: Assessment of observed changes in large-scale indicators of mean climate across climate system components, and their attribution to human influence. The colour coding indicates the assessed confidence in / likelihood of the human contribution as a driver or main driver (specified in that case) where available (see colour key). Otherwise, explanatory text is provided in cells with white background. The relevant chapter section for more detailed information is listed in each table cell.

Change in indicator	Observed change assessment	Human contribution assessment
Atmosphere and water cycle		
Warming of global mean surface air temperature since 1850-1900	{2.3.1, CCB2.3}	*Likely* range of human contribution (0.8°C–1.3°C) encompasses observed warming (0.9°C–1.2°C) {3.3.1}
Warming of the troposphere since 1979	{2.3.1}	Main driver {3.3.1}
Cooling of the lower stratosphere	Since mid-20th century {2.3.1}	Main driver 1979 - mid-1990s {3.3.1}
Large-scale precipitation and upper troposphere humidity changes since 1979	{2.3.1}	{3.3.2, 3.3.3}
Expansion of the zonal mean Hadley Circulation since the 1980s	{2.3.1}	Southern Hemisphere {3.3.3}
Ocean		
Ocean heat content increase since the 1970s	{2.3.3, 2.3.4, 9.2.1, CCB 9.1}	Main driver {3.5.1}
Salinity changes since the mid-20th century	{2.3.3, 2.3.4, 9.2.2}	{3.5.2}
Global mean sea level rise since 1970	{2.3.3, 9.6.1}	Main driver {3.5.3}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Cryosphere		
Arctic sea ice loss since 1979	{2.3.2, 9.3.1}	Main driver {3.4.1}
Reduction in Northern Hemisphere spring snow cover since 1950	{2.3.2, 9.5.3}	{3.4.2}
Greenland Ice Sheet mass loss since 1990s	{2.3.2, 9.4.1}	{3.4.3}
Antarctic Ice Sheet mass loss since 1990s	{2.3.2, 9.4.2}	*Limited evidence & medium agreement* {3.4.3}
Retreat of glaciers	{2.3.2, 9.5.1}	Main driver {3.4.3}
Carbon cycle		
Increased amplitude of the seasonal cycle of atmospheric CO_2 since the early 1960s	{2.3.4}	Main driver {3.6.1}
Acidification of the global surface ocean	{SROCC, 5.3.2, CCB 5.3}	Main driver {3.6.2}
Land climate (extremes, see Table TS.12)		
Mean 2-m land warming since 1850–1900 (about 40% larger than global mean warming)	{2.3.1}	Main driver {3.3.1}
Synthesis		
Warming of the global climate system since preindustrial times	{2.3.5}	{3.8.1}

[END TABLE TS.1 HERE]

Future climate change across a range of atmospheric, cryospheric, oceanic and biospheric indicators depends upon future emissions pathways. Outcomes for a broad range of indicators increasingly diverge through the 21st century across the different SSPs (TS.1.3.1; Figure TS.8). Due to the slow response of the deep ocean and ice sheets, this divergence continues long after 2100, and 21st century emissions choices will have implications for GMSL rise for centuries to millennia. Furthermore, it is *likely* that at least one large volcanic eruption will occur during the 21st century. Such an eruption would reduce global surface temperature for several years, decrease land precipitation, alter monsoon circulation and modify extreme precipitation, at both global and regional scales. {4.3, 4.7, 9.4, 9.6, Cross-Chapter Box 4.1}

[START FIGURE TS.8 HERE]

Figure TS.8: Observed, simulated and projected changes compared to the 1995–2014 average in 4 key indicators of the climate system through to 2100 differentiated by SSP scenario pathway. Past simulations are based on the CMIP6 multi-model ensemble. Future projections are based on the assessed ranges based upon multiple lines of evidence for (a) global surface temperature (Cross-Section Box TS.1) and (b) global ocean heat content and the associated thermosteric sea level contribution to Global Mean Sea Level (GMSL) change (right-hand axis) using a climate model emulator (Cross-Chapter Box 7.1), and CMIP6 simulations for (c) Arctic September sea ice and (d) Global land precipitation. SSP1-1.9 and SSP1-2.6 projections show that reduced GHG emissions lead to a stabilization of global surface temperature, Arctic sea ice area and global land precipitation over the 21st century. SSP1-2.6 shows that emissions reductions have the potential to substantially reduce the increase in ocean heat content and thermosteric sea level rise over the 21st century but that some increase is unavoidable. {4.3, 9.3, 9.6, Figure 4.2, Figure 9.6}

[END FIGURE TS.8 HERE]

Observational records show changes in a wide range of climate extremes that have been linked to human influence on the climate system (Table TS.2). In many cases, the frequency and intensity of future changes in extremes can be directly linked to the magnitude of future projected warming. Changes in extremes are widespread over land since the 1950s, including a *virtually certain* global increase in extreme air

ACCEPTED VERSION SUBJECT TO FINAL EDITING

temperatures and a *likely* intensification in global-scale extreme precipitation. It is *extremely likely* that human influence is the main contributor to the observed increase (decrease) in the likelihood and severity of hot (cold) extremes (Table TS.2). The frequency of extreme temperature and precipitation events in the current climate will change with warming, with warm extremes becoming more frequent (*virtually certain*), cold extremes becoming less frequent (*extremely likely*) and precipitation extremes becoming more frequent in most locations (*very likely*). {9.6.4, 11.2, 11,3, 11.4, 11.6, 11.7, 11.8, 11.9, Box 9.2}

[START TABLE TS.2 HERE]

Table TS.2: Summary table on observed changes in extremes, their attribution since 1950 (except where stated otherwise), and projected changes at +1.5°C, +2°C and +4°C of global warming, on global and continental scale. Warm/hot extremes refer to warmer and/or more frequent hot days and nights and warm spells/heat waves, over most land areas. Cold extremes refer to warmer and/or fewer cold days and nights, and cold spells/cold waves, over most land areas. Drought events are relative to a predominant fraction of land area. For tropical cyclones, observed changes and attribution refer to categories 3-5, while projected changes refer to categories 4-5. Tables 11.1 and 11.2 are more detailed versions of this table, containing in particular information on regional scales. In general, higher warming levels imply stronger projected changes also for indicators where the confidence level does not depend on the warming level and the table does not explicitly quantify the global sensitivity. {9.6, Box 9.2, 11.3, 11.7}

Change in indicator	Observed (since 1950)	Attributed (since 1950)	Projected at GWL (°C) +1.5	+2	+4
Warm/hot extremes: Frequency or intensity	↑	✔ Main driver	↑	↑	↑
Cold extremes: Frequency or intensity	↓	✔ Main driver	↓	↓	↓
Heavy precipitation events: Frequency, intensity and/or amount	↑ Over majority of land regions with good observational coverage	✔ Main driver of the observed intensification of heavy precipitation in land regions	↑ in most land regions	↑	↑ in most land regions
Agricultural and ecological droughts: Intensity and/or duration	↑ for predominant fraction of land area	✔ for predominant fraction of land area	↑ for predominant fraction of land area	↑ for predominant fraction of land area	↑ for predominant fraction of land area
Precipitation associated with tropical cyclones	↑	✔	↑ Rate +11%	↑ Rate +14%	↑ Rate +28%

ACCEPTED VERSION SUBJECT TO FINAL EDITING

TS.2.2 Changes in the Drivers of the Climate System

Since 1750, changes in the drivers of the climate system are dominated by the warming influence of increases in atmospheric GHG concentrations and a cooling influence from aerosols, both resulting from human activities. In comparison there has been negligible long-term influence from solar activity and volcanoes. Concentrations of CO_2, CH_4, and N_2O have increased to levels unprecedented in at least 800,000 years, and there is *high confidence* that current CO_2 concentrations have not been experienced for at least 2 million years. Global mean concentrations of anthropogenic aerosols peaked in the late 20th century and have slowly declined since in northern mid-latitudes, although they continue to increase in South Asia and East Africa (*high confidence*). The total anthropogenic effective radiative forcing (ERF) in 2019, relative to 1750, was 2.72 [1.96 to 3.48] W m^{-2} (*medium confidence*) and has *likely* been growing at an increasing rate since the 1970s. {2.2, 6.4, 7.2, 7.3}

Solar activity since 1900 was high but not exceptional compared to the past 9000 years (*high confidence*). The average magnitude and variability of volcanic aerosols since 1900 has not been unusual compared to at least the past 2500 years (*medium confidence*). However, sporadic strong volcanic eruptions can lead to temporary drops in global surface temperature lasting 2–5 years. {2.2.1, 2.2.2, 2.2.8, CCB4.1}

Atmospheric CO_2 concentrations have changed substantially over millions of years (Figure TS.1). Current levels of atmospheric CO_2 have not been experienced for at least 2 million years (*high confidence*, Figure TS.9a). Over 1750–2019, CO_2 increased by 131.6 ± 2.9 ppm (47.3%). The centennial rate of change of CO_2 since 1850 has no precedent in at least the past 800,000 years (Figure TS.9), and the fastest rates of change over the last 56 million years were at least a factor of 4 lower (*low confidence*) than over 1900–2019. Several networks of high-accuracy surface observations show that concentrations of CO_2 have exceeded 400 ppm, reaching 409.9 (± 0.3) ppm in 2019 (Figure TS.9c). The ERF from CO_2 in 2019 (relative to 1750) was 2.16 Wm^{-2}. {2.2.3, 5.1.2, 5.2.1, 7.3, Box TS.5}

By 2019, concentrations of CH_4 reached 1866.3 (± 3.3) ppb (Figure TS.9c). The increase since 1750 of 1137 ± 10 ppb (157.8%) far exceeds the range over multiple glacial-interglacial transitions of the past 800,000 years (*high confidence*). In the 1990s, CH_4 concentrations plateaued, but started to increase again around 2007 at an average rate of 7.6 ± 2.7 ppb yr^{-1} (2010–2019; *high confidence*). There is *high confidence* that this recent growth is largely driven by emissions from fossil fuel exploitation, livestock, and waste, with ENSO driving multi-annual variability of wetland and biomass burning emissions. In 2019, ERF from CH_4 was 0.54 Wm^{-2}. {2.2.3, 5.2.2, 7.3}

Since 1750, N_2O increased by 62.0 ± 6.0 ppb, reaching a level of 332.1 (± 0.4) ppb in 2019. The increase since 1750 is of comparable magnitude to glacial-interglacial fluctuations of the past 800,000 years (Figure TS.9c). N_2O concentration trends since 1980 are largely driven by a 30% increase in emissions from the expansion and intensification of global agriculture (*high confidence*). By 2019 its ERF was 0.21 Wm^{-2}. {2.2.3, 5.2.3}

[START FIGURE TS.9 HERE]

Figure TS.9: **Changes in well-mixed greenhouse gas (WMGHG) concentrations and Effective Radiative Forcing**. a) Changes in CO_2 from proxy records over the past 3.5 million years; b) Changes in all three WMGHGs from ice core records over the Common Era; c) directly observed WMGHG changes since the mid-20th century; d) Evolution of ERF and components since 1750. Further details on data sources and processing are available in the associated FAIR data table. {2.2, Figures 2.3, 2.4 and 2.10}

[END FIGURE TS.9 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Halogenated gases consist of chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs) and other gases, many of which can deplete stratospheric ozone and warm the atmosphere. In response to controls on production and consumption mandated by the Montreal Protocol on Substances that Deplete the Ozone Layer and its amendments, the atmospheric abundances of most CFCs have continued to decline since AR5. Abundances of of HFCs, which are replacements for CFCs and HCFCs, are increasing (*high confidence*), though increases of the major HCFCs have slowed in recent years. The ERF from halogenated components in 2019 was 0.41 Wm^{-2}. {2.2.4, 6.3.4, 7.3.2}

Tropospheric aerosols mainly act to cool the climate system, directly by reflecting solar radiation, and indirectly through enhancing cloud reflectance. Ice cores show increases in aerosols across the Northern Hemisphere mid-latitudes since 1700, and reductions since the late 20th century (*high confidence*). Aerosol optical depth (AOD), derived from satellite- and ground-based radiometers, has decreased since 2000 over the mid-latitude continents of both hemispheres, but increased over South Asia and East Africa (*high confidence*). Trends in AOD are more pronounced from sub-micrometre aerosols for which the anthropogenic contribution is particularly large. Global carbonaceous aerosol budgets and trends remain poorly characterised due to limited observations, but black carbon (BC), a warming aerosol component, is declining in several regions of the Northern Hemisphere (*low confidence*). Total aerosol ERF in 2019, relative to 1750, is −1.1 [−1.7 to −0.4] W m^{-2} (*medium confidence*), and *more likely than not* became less negative since the late 20th century, with *low confidence* in the magnitude of post-2014 changes due to conflicting evidence (TS.3.1). {2.2.6, 6.2.1, 6.3.5, 6.4.1, 7.3.3}

There is *high confidence* that tropospheric ozone has been increasing from 1750 in response to anthropogenic changes in ozone precursor emissions (nitrogen oxides, carbon monoxide, non-methane volatile organic compounds, and methane), but with *medium confidenc*e in the magnitude of this change, due to limited observational evidence and knowledge gaps. Since the mid-20th century, tropospheric ozone surface concentrations have increased by 30–70% across the Northern Hemisphere (*medium confidence*); since the mid-1990s free tropospheric ozone has increased by 2–7% per decade in most northern mid-latitude regions, and 2–12% per decade in sampled tropical regions. Future changes in surface ozone concentrations will be primarily driven by changes in precursor emissions rather than climate change (*high confidence*). Stratospheric ozone has declined between 60˚S–60˚N by 2.2% from 1964–1980 to 2014–2017 (*high confidence*), with the largest declines during 1980–1995. The strongest loss of stratospheric ozone continues to occur in austral spring over Antarctica (ozone hole), with emergent signs of recovery after 2000. The 1750–2019 ERF for total (stratospheric and tropospheric) ozone is 0.47 [0.24 to 0.71] W m^{-2}, which is dominated by tropospheric ozone changes. {2.2.5; 6.3.2., 7.3.2, 7.3.5}

The global mean abundance of hydroxyl (OH) radical, or 'oxidising capacity', chemically regulates the lifetimes of many short-lived climate forcers (SLCFs), and therefore the radiative forcing of methane, ozone, secondary aerosols and many halogenated species. Model estimates suggest no significant change in oxidising capacity from 1850 to 1980 (*low confidence*). Increases of about 9% over 1980–2014 computed by ESMs and carbon cycle models are not confirmed by observationally constrained inverse models, rendering an overall *medium confidence* in stable OH or positive trends since the 1980s, and implying that OH is not the primary driver of recent observed growth in CH_4. {6.3.6, CCB5.2}

Land use and land-cover change exert biophysical and biogeochemical effects. There is *medium confidence* that the biophysical effects of land-use change since 1750, most notably the increase in global albedo, have had an overall cooling on climate, whereas biogeochemical effects (i.e., changes in GHG and volatile organic compound emissions or sinks) led to net warming. Overall land use and land cover ERF is estimated at -0.2 [-0.3 to -0.1] W m^{-2}. {2.2.7, 7.3.4, SRCCL 2.5}

The total anthropogenic ERF (Figure TS.9) in 2019 relative to 1750 was 2.72 [1.96 to 3.48] W m^{-2} (Figure TS.9), dominated by GHGs (positive ERF) and partially offset by aerosols (negative ERF). The rate of change of ERF *likely* has increased since the 1970s, mainly due to growing CO_2 concentrations and less negative aerosol ERF. {2.2.8, 7.3}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

TS.2.3 Upper Air Temperatures and Atmospheric Circulation

The effects of human-induced climate change have been clearly identified in observations of atmospheric temperature and some aspects of circulation, and these effects are *likely* to intensify in the future. Tropospheric warming and stratospheric cooling are *virtually certain* to continue with continued net emissions of greenhouse gases. Several aspects of the atmospheric circulation have *likely* changed since the mid-20th century, and human influence has *likely* contributed to the observed poleward expansion of the Southern Hemisphere Hadley Cell and *very likely* contributed to the observed poleward shift of the Southern Hemisphere extratropical jet in summer. It is *likely* that the mid-latitude jet will shift poleward and strengthen, accompanied by a strengthening of the storm track in the Southern Hemisphere by 2100 under the high CO_2 emissions scenarios. It is *likely* that the proportion of intense tropical cyclones has increased over the last four decades and that this cannot be explained entirely by natural variability. There is *low confidence* in observed recent changes in the total number of extratropical cyclones over both hemispheres. The proportion of tropical cyclones which are intense is expected to increase (*high confidence*) but the total global number of tropical cyclones is expected to decrease or remain unchanged (*medium confidence*). {2.3, 3.3, 4.3, 4.4, 4.5, 8.3, 8.4, 11.7}

The troposphere has warmed since at least the 1950s, and it is *virtually certain* that the stratosphere has cooled. It is *very likely* that human-induced increases in GHGs were the main driver of tropospheric warming since 1979. It is *extremely likely* that anthropogenic forcing, both from increases in GHG concentration and depletion of stratospheric ozone due to ozone-depleting substances, was the main driver of upper stratospheric cooling since 1979. It is *very likely* that global mean stratospheric cooling will be larger for scenarios with higher atmospheric CO_2 concentrations. In the tropics, since at least 2001 (when new techniques permit more robust quantification), the upper troposphere has warmed faster than the near-surface (*medium confidence*) (Figure TS.10). There is *medium confidence* that most CMIP5 and CMIP6 models overestimate the observed warming in the upper tropical troposphere over the period 1979–2014, in part because they overestimate tropical SST warming. It is *likely* that future tropical upper tropospheric warming will be larger than at the tropical surface. {2.3.1, 3.3.1, 4.5.1}

[START FIGURE TS.10 HERE]

Figure TS.10: Observed and projected upper air temperature and circulation changes. Upper panels: Left: Zonal cross-section of temperature trends for 2002-2019 in the upper troposphere region for the ROM SAF radio-occultation dataset. Middle: Change in the annual and zonal mean atmospheric temperature (°C) in 2081-2100 in SSP1-2.6 relative to 1995-2014 for 36 CMIP6 models. Right: the same in SSP3-7.0 for 32 models. Lower panels: Left: Long-term mean (thin black colour) and linear trend (colour) of zonal mean DJF zonal winds for ERA5. Middle: multi-model mean change in annual and zonal mean wind (m s^{-1}) in 2081-2100 in SSP1-2.6 relative to 1995-2014 based on 34 CMIP6 models. The 1995-2014 climatology is shown in contours with spacing 10 m s^{-1}. Right: the same for SSP3-7.0 for 31 models. {2.3.1, 4.5.1, Figures 2.12, 2.18, and 4.26}

[END FIGURE TS.10 HERE]

The Hadley Circulation has *likely* widened since at least the 1980s, predominantly in the Northern Hemisphere, although there is only *medium confidence* in the extent of the changes. This has been accompanied by a strengthening of the Hadley Circulation in the Northern Hemisphere (*medium confidence*). It is *likely* that human influence has contributed to the poleward expansion of the zonal mean Hadley cell in the Southern Hemisphere since the 1980s, which is projected to further expand with global warming (*high confidence*). There is *medium confidence* that the observed poleward expansion in the Northern Hemisphere is within the range of internal variability. {2.3.1, 3.3.3, 8.4.3}

Since the 1970s near-surface average winds have *likely* weakened over land. Over the ocean, near-surface average winds *likely* strengthened over 1980–2000, but divergent estimates lead to *low confidence* thereafter.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Extratropical storm tracks have *likely* shifted poleward since the 1980s. There is *low confidence* in projected poleward shifts of the Northern Hemisphere mid-latitude jet and storm tracks due to large internal variability and structural uncertainty in model simulations. There is *medium confidence* in a projected decrease of frequency of atmospheric blocking over Greenland and the North Pacific in boreal winter in 2081–2100 under the SSP3-7.0 and SSP5-8.5 scenarios. There is *high confidence* that Southern Hemisphere storm tracks and associated precipitation have migrated polewards over recent decades, especially in the austral summer and autumn, associated with a trend towards more positive phases of the Southern Annular Mode (SAM) (TS.4.2.2) and the strengthening and southward shift of the Southern Hemisphere extratropical jet in austral summer. In the long term (2081–2100), the Southern Hemisphere mid-latitude jet is *likely* to shift poleward and strengthen under SSP5-8.5 scenario relative to 1995–2014, accompanied by an increase in the SAM (TS.4.2.2). It is *likely* that wind speeds associated with extratropical cyclones will strengthen in the Southern Hemisphere storm track for SSP5-8.5. There is *low confidence* in the potential role of Arctic warming and sea ice loss on historical or projected mid-latitude atmospheric variability. {2.3.1, 3.3.3, 3.7.2, 4.3.3, 4.4.3, 4.5.1, 4.5.3, 8.2.2, 8.3.2, Cross-Chapter Box 10.1}

It is *likely* that the proportion of major (Category 3–5) tropical cyclones (TCs) and the frequency of rapid TC intensification events have increased over the past four decades. The average location of peak TC wind-intensity has *very likely* migrated poleward in the western North Pacific Ocean since the 1940s, and TC forward translation speed has *likely* slowed over the contiguous USA since 1900. It is *likely* that the poleward migration of TCs in the western North Pacific and the global increase in TC intensity rates cannot be explained entirely by natural variability**.** There is *high confidence* that average peak TC wind speeds and the proportion of Category 4–5 TCs will increase with warming and that peak winds of the most intense TCs will increase. There is *medium confidence* that the average location where TCs reach their maximum wind-intensity will migrate poleward in the western North Pacific Ocean, while the total global frequency of TC formation will decrease or remain unchanged with increasing global warming (*medium confidence*). {11.7}

There is *low confidence* in observed recent changes in the total number of extratropical cyclones over both hemispheres. There is also *low confidence* in past-century trends in the number and intensity of the strongest extratropical cyclones over the Northern Hemisphere due to the large interannual-to-decadal variability and temporal and spatial heterogeneities in the volume and type of assimilated data in atmospheric reanalyses, particularly before the satellite era. Over the Southern Hemisphere, it is *likely* that the number of extratropical cyclones with low central pressures (<980 hPa) has increased since 1979. The frequency of intense extratropical cyclones is projected to decrease (*medium confidence*). Projected changes in the intensity depend on the resolution of climate models (*medium confidence*). There is *medium confidence* that wind speeds associated with extratropical cyclones will change following changes in the storm tracks. {2.3.1, 3.3.3, 4.5.1, 4.5.3, 8.3.2, 8.4.2, 11.7.2, 11.7.2}

[START BOX TS.3 HERE]

Box TS.3: Low-Likelihood, High-Warming Storylines

Future global warming exceeding the assessed *very likely* range cannot be ruled out and is potentially associated with the highest risks for society and ecosystems. Such low-likelihood, high-warming storylines tend to exhibit substantially greater changes in the intensity of regional drying and wetting than the multi-model mean. Even at levels of warming within the *very likely* range, global and regional low-likelihood outcomes might occur, such as large precipitation changes, additional sea level rise associated with collapsing ice sheets, or abrupt ocean circulation changes. While there is *medium confidence* that the Atlantic Meridional Overturning circulation (AMOC) will not experience an abrupt collapse before 2100, if it were to occur, it would *very likely* cause abrupt shifts in regional weather patterns and water cycle. The probability of these low-likelihood outcomes increases with higher global warming levels. If the real-world climate sensitivity lies at the high end of the assessed range, then global and regional changes substantially outside the *very likely* range projections occur for a given emissions scenario. With increasing global warming, some very rare extremes and some compound events (multivariate or concurrent extremes) with low likelihood in past and current climate will become more frequent, and there is a higher chance that events unprecedented

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in the observational record occur (*high confidence*). Finally, low likelihood, high-impact outcomes may also arise from a series of very large volcanic eruptions that could substantially alter the 21st century climate trajectory compared to SSP-based Earth system model projections. {Cross-Chapter Box 4.1, 4.3, 4.4, 4.8, 7.3, 7.4, 7.5, 8.6, 9.2, 9.6, Box TS.4, Box 9.4, Box 11.2, CCB 12.1}

Previous IPCC reports largely focused their assessment on the projected *very likely* range of future surface warming and associated climate change. However, a comprehensive risk assessment also requires considering the potentially larger changes in the physical climate system that are *unlikely* or *very unlikely* but possible and potentially associated with the highest risks for society and ecosystems (Figure TS.6). Since AR5, the development of physical climate storylines of high warming has emerged as a useful approach for exploring the future risk space that lies outside of the IPCC *very likely* range projections. {4.8}

Uncertainty in the true values of equilibrium climate sensitivity (ECS) and transient climate response (TCR) dominate uncertainty in projections of future warming under moderate to strong emissions scenarios (TS.3.2). A real-world ECS higher than the assessed *very likely* range (2°C–5°C) would require a strong historical aerosol cooling and/or a trend towards stronger warming from positive feedbacks linked to changes in SST patterns (pattern effects), combined with a strong positive cloud feedback and substantial biases in paleoclimate reconstructions – each of which is assessed as either *unlikely* or *very unlikely*, but not ruled out. Since CMIP6 contains several ESMs that exceed the upper bound of the assessed *very likely* range in future surface warming, these models can be used to develop low-likelihood, high warming storylines to explore risks and vulnerabilities, even in the absence of a quantitative assessment of likelihood. {4.3.4, 4.8, 7.3.2, 7.4.4, 7.5.2, 7.5.5, 7.5.7}

CMIP6 models with surface warming outside, or close to, the upper bound of the *very likely* range exhibit patterns of large widespread temperature and precipitation changes that differ substantially from the multi-model mean in all scenarios. For SSP5-8.5, the high-warming models exhibit widespread warming of more than 6°C over most extratropical land regions and parts of the Amazon. In the Arctic, annual mean temperatures increase by more than 10°C relative to present-day, corresponding to about 30% more than the best estimate of warming. Even for SSP1-2.6, high-warming models show on average 2°C–3°C warming relative to present-day conditions over much of Eurasia and North America (about 40% more than the best estimate of warming) and more than 4°C warming relative to the present over the Arctic (Box TS.3, Figure 1) in 2081–2100. Such a high global warming storyline would imply that the remaining carbon budget consistent with a 2°C warming is smaller than the assessed *very likely* range. Put another way, even if a carbon budget that *likely* limits warming to 2°C is met, a low-likelihood, high-warming storyline would result in warming of 2.5°C or more. {4.8}

CMIP6 models with global warming close to the upper bound of the assessed *very likely* warming range tend to exhibit greater changes in the intensity of regional drying and wetting than the multi-model mean. Furthermore, these model projections show a larger area of drying and tend to show a larger fraction of strong precipitation increases than the multi-model mean. However, regional precipitation changes arise from both thermodynamic and dynamic processes so that the most pronounced global warming levels are not necessarily associated with the strongest precipitation response. Abrupt human-caused changes to the water cycle cannot be ruled out. Positive land surface feedbacks, involving vegetation and dust, can contribute to abrupt changes in aridity, but there is only *low confidence* that such changes will occur during the 21st century. Continued Amazon deforestation, combined with a warming climate, raises the probability that this ecosystem will cross a tipping point into a dry state during the 21st century (*low confidence*). {4.8, 8.6.2, Box TS.9}

While there is *medium confidence* that the projected decline in the Atlantic Meridional Overturning Circulation (AMOC) (TS.2.4) will not involve an abrupt collapse before 2100, such a collapse might be triggered by an unexpected meltwater influx from the Greenland Ice Sheet. If an AMOC collapse were to occur, it would *very likely* cause abrupt shifts in the weather patterns and water cycle, such as a southward shift in the tropical rain belt, and could result in weakening of the African and Asian monsoons and strengthening of Southern Hemisphere monsoons. {4.7.2, 8.6.1, 9.2.3, Box TS.9, Box TS.13}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Very rare extremes and compound or concurrent events, such as the 2018 concurrent heatwaves across the Northern Hemisphere, are often associated with large impacts. The changing climate state is already altering the likelihood of extreme events, such as decadal droughts and extreme sea levels, and will continue to do so under future warming. Compound events and concurrent extremes contribute to increasing probability of low-likelihood, high-impact outcomes, and will become more frequent with increasing global warming (*high confidence*). Higher warming levels increase the likelihood of events unprecedented in the observational record. {Box 11.2, 9.6.4}

Finally, low likelihood storylines need not necessarily relate solely to the human-induced changes in climate. A low-likelihood, high-impact outcome, consistent with historical precedent in the past 2,500 years, would be to see several large volcanic eruptions that could greatly alter the 21st century climate trajectory compared to SSP-based Earth system model projections. {Cross-Chapter Box 4.1}

[START BOX TS.3, FIGURE 1 HERE]

Box TS.3, Figure 1: High-warming storylines. (a) CMIP6 multi-model mean linearly scaled to the assessed best global surface temperature estimate for SSP1-2.6 in 2081–2100 relative to 1995–2014, (b) mean across five high-warming models with global surface temperature changes warming nearest to the upper bound of the assessed very likely range, (c) mean across five very high-warming models with global surface temperature changes warming higher than the assessed very likely. (d-f) Same as (a-c) but for SSP5-8.5. Note the different colour bars in (a-c) and (d-f). {4.7, Figure 4.41}

[END BOX TS.3, FIGURE 1 HERE]

[END BOX TS.3 HERE]

TS.2.4 The Ocean

Observations, models and paleo-evidence indicate that recently observed changes in the ocean are unprecedented for centuries to millennia (*high confidence*). Over the past four to six decades, it is *virtually certain* that the global ocean has warmed, with human influence *extremely likely* the main driver since the 1970s, making climate change irreversible over centuries to millennia (*medium confidence*). It is *virtually certain* that upper ocean salinity contrasts have increased since the 1950s and *extremely likely* that human influence has contributed. It is *virtually certain* that upper ocean stratification has increased since 1970 and that sea water pH has declined globally over the last 40 years, with human influence the main driver of the observed ocean acidification (*virtually certain*). There is *high confidence* that marine heatwaves have become more frequent in the 20th century, and most of them have been attributed to anthropogenic warming since 2006 (*very likely*). There is *high confidence* that oxygen levels have dropped in many regions since the mid 20th century and that the geographic range of many marine organisms has changed over the last two decades. The amount of ocean warming observed since 1971 will *likely* at least double by 2100 under a low warming scenario (SSP1-2.6) and will increase by 4-8 times under a high warming scenario (SSP5-8.5). Stratification (*virtually certain*), acidification (*virtually certain*), deoxygenation (*high confidence*) and marine heatwave frequency (*high confidence*) will continue to increase in the 21st century. While there is *low confidence* in 20th century AMOC change, it is *very likely* that AMOC will decline over the 21st century (Figure TS.11). {2.3, 3.5, 3.6, 4.3, 5.3, 7.2, 9.2, 9.4, 9.6, Box 9.2, 12.4}

It is *virtually certain* that the global ocean has warmed since at least 1971, representing about 90% of the increase in the global energy inventory (TS.3.1). The ocean is currently warming faster than at any other time since at least the last deglacial transition (*medium confidence*), with warming extending to depths well below 2000 m (*very high confidence*). It is *extremely likely* that human influence was the main driver of ocean warming. Ocean warming will continue over the 21st century (*virtually certain*), and will *likely* continue until at least to 2300 even for low CO_2 emissions scenarios. Ocean warming is irreversible over centuries to millennia (*medium confidence*), but the magnitude of warming is scenario-dependent from about

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the mid-21st century (*medium confidence*). The warming will not be globally uniform, with heat primarily stored in Southern Ocean water-masses and weaker warming in the subpolar North Atlantic (*high confidence*). Limitations in the understanding of feedback mechanisms limit our confidence in future ocean warming close to Antarctica and how this will affect sea ice and ice shelves. {2.3.3, 3.5.1, 4.7.2, 7.2.2, 9.2.2, 9.2.3, 9.2.4, 9.3.2, 9.6.1; Cross-Chapter Box 9.1}

Global mean SST has increased since the beginning of the 20th century by 0.88 [0.68 to 1.01] °C, and it is *virtually certain* it will continue to increase throughout the 21st century with increasing hazards to marine ecosystems (*medium confidence*). Marine heatwaves have become more frequent over the 20th century (*high confidence*), approximately doubling in frequency (*high confidence*) and becoming more intense and longer since the 1980s (*medium confidence*). Most of the marine heatwaves over 2006–2015 have been attributed to anthropogenic warming (*very likely*). Marine heatwaves will continue to increase in frequency, with a *likely* global increase of 2–9 times in 2081–2100 compared to 1995–2014 under SSP1-2.6, and 3–15 times under SSP5-8.5 (Figure TS.11a), with the largest changes in the tropical and Arctic ocean. {2.3.1, 9.2.1; Box 9.2; 12.4.8; Cross-Chapter Box 2.3}

Observed upper ocean stratification (0–200 m) has increased globally since at least 1970 *(virtually certain)*. Based on recent refined analyses of the available observations, there is *high confidence* that it increased by 4.9 ±1.5% from 1970–2018, which is about twice as much as assessed in the SROCC, and will continue to increase throughout the 21st century at a rate depending on the emissions scenario (*virtually certain*). {2.3.3, 9.2.1}

It is *virtually certain* that since 1950 near-surface high-salinity regions have become more saline, while low-salinity regions have become fresher, with *medium confidence* that this is linked to an intensification of the hydrological cycle (Box TS.6). It is *extremely likely* that human influence has contributed to this salinity change and that the large-scale pattern will grow in amplitude over the 21st century (*medium confidence*). {2.3.3, 3.5.2, 9.2.2, 12.4.8}

The AMOC was relatively stable during the past 8,000 years (*medium confidence*). There is *low confidence* in the quantification of AMOC changes in the 20th century because of *low agreement* in quantitative reconstructed and simulated trends, missing key processes in both models and measurements used for formulating proxies, and new model evaluations. Direct observational records since the mid-2000s are too short to determine the relative contributions of internal variability, natural forcing and anthropogenic forcing to AMOC change (*high confidence*). An AMOC decline over the 21st century is *very likely* for all SSP scenarios; a possible abrupt decline is assessed further in Box TS.3 (Figure TS.11b). {2.3.3, 3.5.4, 4.3.2, 8.6.1, 9.2.3, Cross-Chapter Box 12.3}

There is *high confidence* that many ocean currents will change in the 21st century in response to changes of wind stress. There is *low confidence* in 21st century change of Southern Ocean circulation, despite *high confidence* that it is sensitive to changes in wind patterns and increased ice-shelf melt. Western boundary currents and subtropical gyres have shifted poleward since 1993 (*medium confidence*). Subtropical gyres, the East Australian Current Extension, the Agulhas Current, and the Brazil Current are projected to intensify in the 21st century in response to changes in wind stress, while the Gulf Stream and the Indonesian Throughflow are projected to weaken (*medium confidence*). All of the four main eastern boundary upwelling systems are projected to weaken at low latitudes and intensify at high latitudes in the 21st century (*high confidence*). {2.3.3, 9.2.3}

It is *virtually certain* that surface pH has declined globally over the last 40 years and that the main driver is uptake of anthropogenic CO_2. Ocean acidification and associated reductions in the saturation state of calcium carbonate – a constituent of skeletons or shells of a variety of marine organisms – is expected to increase in the 21st century under all emissions scenarios (*high confidence*). There is *very high confidence* that present-day surface pH values are unprecedented for at least 26,000 years and current rates of pH change are unprecedented since at least that time. Over the past 2–3 decades, a pH decline in the ocean interior has been observed in all ocean basins (*high confidence*) (Figure TS.11d). {2.3.3, 2.3.4, 3.6.2, 4.3.2, 5.3.2, 5.3.3, 5.6.3, 12.4.8}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Open-ocean deoxygenation and expansion of oxygen minimum zones has been observed in many areas of the global ocean since the mid 20th century (*high confidence*), in part due to human influence (*medium confidence*). Deoxygenation is projected to continue to increase with ocean warming (*high confidence*) (Figure TS.11c). Higher climate sensitivity and reduced ocean ventilation in CMIP6 compared to CMIP5 results in substantially greater projections of subsurface (100–600 m) oxygen decline than reported in SROCC for the period 2080–2099. {2.3.3, 2.3.4, Cross-Chapter Box 2.4, 3.6.2, 5.3.3, 12.4.8}

Over at least the last two decades, the geographic range of many marine organisms has shifted towards the poles and towards greater depths (*high confidence*), indicative of shifts towards cooler waters. The range of a smaller subset of organisms has shifted equatorward and to shallower depths (*high confidence*). Phenological metrics associated with the life cycles of many organisms have also changed over the last two decades or longer (*high confidence*). Since the changes in the geographical range of organisms and their phenological metrics have been observed to differ with species and location, there is the possibility of disruption to major marine ecosystems. {2.3.4}

[START FIGURE TS.11 HERE]

Figure TS.11: **Past and future ocean and ice sheet changes.** Observed and simulated historical changes and projected future changes under varying greenhouse gas emissions scenarios. Simulated and projected ocean changes are shown as CMIP6 ensemble mean, and 5-95% range (shading) is provided for scenario SSP1-2.6 and SSP3-7.0 (except in panel a where range provided for scenario SSP1-2.6 and SSP5-8.5). Mean and 5-95% range in 2100 are shown as vertical bars on the right-hand side of each panel. (a) Change in multiplication factor in surface ocean marine heatwave days relative to 1995-2014 (defined as days exceeding the 99th percentile in SST from 1995-2014 distribution). Assessed observational change span 1982-2019 from AVHRR satellite SST. (b) AMOC transport relative to 1995-2014 (defined as maximum transport at 26°N). Assessed observational change spans 2004-2018 from the RAPID array smoothed with a 12-month running mean (shading around the mean shows the 12-month running standard deviation around the mean). (c) Global mean percent change in ocean oxygen (100–600 m depth), relative to 1995-2014. Assessed observational trends and *very likely* range are from the SROCC assessment, and spans 1970–2010 centered on 2005. (d) Global mean surface pH. Assessed observational change span 1985-2019, from the CMEMS SOCAT-based reconstruction (shading around the global mean shows the 90% confidence interval). (e), (f): Ice sheet mass changes. Projected ice sheet changes are shown as median, 5-95% range (light shading), and 17-83% range (dark shading) of cumulative mass loss and sea level equivalent from ISMIP6 emulation under SSP1-26 and SSP5-85 (shading and bold line), with individual emulated projections as thin lines. Median (dot), 17-83% range (thick vertical bar), and 5-95% range (thin vertical bar) in 2100 are shown as vertical bars on the right-hand side of each panel, from ISMIP6, ISMIP6 emulation, and LARMIP-2. Observation-based estimates: For Greenland (e), for 1972-2018 (Mouginot), for 1992-2016 (Bamber), for 1992-2020 (IMBIE) and total estimated mass loss range for 1840-1972 (Box). For Antarctica (f), estimates based on satellite data combined with simulated surface mass balance and glacial isostatic adjustment for 1992-2020 (IMBIE), 1992-2016 (Bamber), and 1979-2017 (Rignot). Left inset maps: mean Greenland elevation changes 2010-2017 derived from CryoSat-2 radar altimetry (e) and mean Antarctica elevation changes 1978-2017 derived from restored analog radar records (f). Right inset maps: ISMIP6 model mean (2093- 2100) projected changes under the MIROC5 climate model for the RCP8.5 scenario. {Box 9.2, 2.3.3, 2.3.4, 3.5.4, 4.3.2, 5.3.2, 5.3.3, 5.6.3, 9.2.3, 9.4.1, 9.4.2, Box 9.2 Figure 1, Figure 9.10, Figure 9.17, Figure 9.18}

[END FIGURE TS.11 HERE]

TS.2.5 The Cryosphere

Over recent decades, widespread loss of snow and ice has been observed, and several elements of the cryosphere are now in states unseen in centuries (*high confidence*). Human influence was *very likely* the main driver of observed reductions in Arctic sea ice since the late 1970s (with late-summer sea ice loss *likely* unprecedented for at least 1000 years) and the widespread retreat of glaciers (unprecedented in at least the last 2,000 years, *medium confidence*). Furthermore, human influence *very likely* contributed to the observed

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Northern Hemisphere spring snow cover decrease since 1950. By contrast, Antarctic sea ice area experienced no significant net change since 1979, and there is only *low confidence* in its projected changes. The Arctic Ocean is projected to become practically sea ice-free in late summer under high CO_2 emissions scenarios by the end of the 21st century (*high confidence*). It is *virtually certain* that further warming will lead to further reductions of Northern Hemisphere snow cover, and there is *high confidence* that this is also the case for near-surface permafrost volume. Glaciers will continue to lose mass at least for several decades even if global temperature is stabilized (*very high confidence*), and mass loss over the 21st century is *virtually certain* for the Greenland Ice Sheet and *likely* for the Antarctic Ice Sheet. Deep uncertainty persists with respect to the possible evolution of the Antarctic Ice Sheet within the 21st century and beyond, in particular due to the potential instability of the West Antarctic Ice Sheet. {2.3, 3.4, 4.3, 8.3, 9.3-9.6, Box 9.4, 12.4}

Current Arctic sea ice coverage levels (both annual and late summer) are at their lowest since at least 1850 (*high confidence*), and for late summer for the past 1,000 years (*medium confidence*). Since the late 1970s, Arctic sea ice area and thickness have decreased in both summer and winter, with sea ice becoming younger, thinner and more dynamic (*very high confidence*). It is *very likely* that anthropogenic forcing, mainly due to greenhouse gas increases, was the main driver of this loss, although new evidence suggests that anthropogenic aerosol forcing has offset part of the greenhouse gas–induced losses since the 1950s (*medium confidence*). The annual Arctic sea ice area minimum will *likely* fall below 1 million km^2 at least once before 2050 under all assessed SSP scenarios. This practically sea ice-free state will become the norm for late summer by the end of the 21st century in high CO_2 emissions scenarios (*high confidence*). Arctic summer sea ice varies approximately linearly with global surface temperature, implying that there is no tipping point and observed/projected losses are potentially reversible (*high confidence*). {2.3.2, 3.4.1, 4.3.2, 9.3.1, 12.4.9}

For Antarctic sea ice, there is no significant trend in satellite-observed sea ice area from 1979 to 2020 in both winter and summer, due to regionally opposing trends and large internal variability. Due to mismatches between model simulations and observations, combined with a lack of understanding of reasons for substantial inter-model spread, there is *low confidence* in model projections of future Antarctic sea ice changes, particularly at the regional level. {2.3.2, 3.4.1, 9.3.2}

In permafrost regions, increases in ground temperatures in the upper 30 m over the past three to four decades have been widespread (*high confidence*). For each additional 1°C of warming (up to 4°C above the 1850–1900 level), the global volume of perennially frozen ground to 3 m below the surface is projected to decrease by about 25% relative to the present volume (*medium confidence*). However, these decreases may be underestimated due to an incomplete representation of relevant physical processes in ESMs (*low confidence*). Seasonal snow cover is treated in TS.2.6. {2.3.2, 9.5.2, 12.4.9}

There is *very high confidence* that, with few exceptions, glaciers have retreated since the second half of the 19th century; this behaviour is unprecedented in at least the last 2,000 years (*medium confidence*). Mountain glaciers *very likely* contributed 67.2 [41.8 to 92.6] mm to the observed GMSL change between 1901 and 2018. This retreat has occurred at increased rates since the 1990s, with human influences *very likely* being the main driver. Under RCP2.6 and RCP8.5, respectively, glaciers are projected to lose 18% ± 13% and 36% ± 20% of their current mass over the 21st century (*medium confidence*). {2.3.2, 3.4.3, 9.5.1, 9.6.1}

The Greenland Ice Sheet was smaller than at present during the Last Interglacial period (roughly 125,000 years ago) and the mid-Holocene (roughly 6,000 years ago) (*high confidence*). After reaching a recent maximum ice mass at some point between 1450 and 1850, the ice sheet retreated overall, with some decades *likely* close to equilibrium (i.e., mass loss approximately equalling mass gained). It is *virtually certain* that the Greenland Ice Sheet has lost mass since the 1990s, with human influence a contributing factor (*medium confidence*). There is *high confidence* that annual mass changes have been consistently negative since the early 2000s. Over the period 1992–2020, Greenland *likely* lost 4890 ± 460 Gt of ice, contributing 13.5 ± 1.3 mm to global mean sea level rise. There is *high confidence* that Greenland ice mass losses are increasingly dominated by surface melting and runoff, with large interannual variability arising from changes in surface mass balance. Projections of future Greenland ice-mass loss (Box TS.4, Table 1; Figure TS.11e) are dominated by increased surface melt under all emissions scenarios (*high confidence*). Potential irreversible long-term loss of the Greenland Ice Sheet, and of parts of the Antarctic Ice Sheet, is assessed in Box TS.9.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

{2.3.2, 3.4.3, 9.4.1, 9.4.2, 9.6.3, Atlas.11.2}

It is *likely* that the Antarctic Ice Sheet has lost 2670 ± 530 Gt, contributing 7.4 ± 1.5 mm to global mean sea level rise over 1992–2020. The total Antarctic ice mass losses were dominated by the West Antarctic Ice Sheet, with combined West Antarctic and Peninsula annual loss rates increasing since about 2000 (*very high confidence*). Furthermore, it is *very likely* that parts of the East Antarctic Ice Sheet have lost mass since 1979. Since the 1970s, snowfall has *likely* increased over the western Antarctic Peninsula and eastern West Antarctica, with large spatial and interannual variability over the rest of Antarctica. Mass losses from West Antarctic outlet glaciers, mainly induced by ice shelf basal melt (*high confidence*), outpace mass gain from increased snow accumulation on the continent (*very high confidence*). However, there is only *limited evidence*, with *medium agreement*, of anthropogenic forcing of the observed Antarctic mass loss since 1992 (with *low confidence* in process attribution). Increasing mass loss from ice shelves and inland discharge will *likely* continue to outpace increasing snowfall over the 21st century (Figure TS.11f). Deep uncertainty persists with respect to the possible evolution of the Antarctic Ice Sheet along high-end mass-loss storylines within the 21st century and beyond, primarily related to the abrupt and widespread onset of Marine Ice Sheet Instability and Marine Ice Cliff Instability. {2.3.2, 3.4.3, 9.4.2, 9.6.3, Box 9.4, Atlas.11.1, Box TS.3, Box TS.4}

[START BOX TS.4 HERE]

Box TS.4: Sea Level

Global mean sea level (GMSL) increased by 0.20 [0.15 to 0.25] m over the period 1901 to 2018 with a rate of rise that has accelerated since the 1960s to 3.7 [3.2 to 4.2] mm yr^{-1} for the period 2006–2018 (*high confidence*). Human activity was *very likely* the main driver of observed GMSL rise since 1970, and new observational evidence leads to an assessed sea level rise over the period 1901 to 2018 that is consistent with the sum of individual components contributing to sea level rise, including expansion due to ocean warming and melting of glaciers and ice sheets (*high confidence*). It is *virtually certain* that GMSL will continue to rise over the 21st century in response to continued warming of the climate system (Box TS.4, Figure 1). Sea level responds to GHG emissions more slowly than global surface temperature, leading to weaker scenario dependence over the 21st century than for global surface temperature (*high confidence*). This slow response also leads to long-term committed sea level rise, associated with ongoing ocean heat uptake and the slow adjustment of the ice sheets, that will continue over the centuries and millennia following cessation of emissions (*high confidence*). By 2100, GMSL is projected to rise by 0.28–0.55 m (*likely* range) under SSP1-1.9 and 0.63–1.02 m (*likely* range) under SSP5-8.5 relative to the 1995–2014 average (*medium confidence*). Under the higher CO_2 emissions scenarios, there is deep uncertainty in sea level projections for 2100 and beyond associated with the ice-sheet responses to warming. In a low-likelihood, high-impact storyline and a high CO_2 emissions scenario, ice-sheet processes characterized by deep uncertainty could drive GMSL rise up to about 5 m by 2150. Given the long-term commitment, uncertainty in the timing of reaching different GMSL rise levels is an important consideration for adaptation planning. {2.3, 3.4, 3.5, 9.6, Box 9.4, Box TS.9 Cross-Chapter Box 9.1, Table 9.5}

GMSL change is driven by warming or cooling of the ocean (and the associated expansion/contraction) and changes in the amount of ice and water stored on land. Paleo-evidence shows that GMSL has been about 70 m higher and 130 m lower than present within the past 55 million years and was *likely* 5 to 10 m higher during the Last Interglacial (Box TS.2, Figure 1). Sea level observations show that GMSL rose by 0.20 [0.15 to 0.25] m over the period 1901–2018 at an average rate of 1.7 [1.3 to 2.2] mm yr^{-1}. New analyses and paleo-evidence since the AR5 show this rate is *very likely* faster than during any century over at least the last three millennia (*high confidence*). Since the AR5, there is strengthened evidence for an increase in the rate of GMSL rise since the mid-20th century, with an average rate of 2.3 [1.6–3.1] mm yr^{-1} over the period 1971–2018 increasing to 3.7 [3.2–4.2] mm yr^{-1} for the period 2006–2018 (*high confidence*). {2.3.3.3, 9.6.1, 9.6.2}

GMSL will continue to rise throughout the 21st century (Box TS.4, Figure 1a). Considering only those processes in whose projections we have at least *medium confidence*, relative to the period 1995–2014,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GMSL is projected to rise between 0.18 m (0.15–0.23 m, *likely range*) (SSP1-1.9) and 0.23 m (0.20–0.30 m, *likely range*) (SSP5-8.5) by 2050. By 2100, the projected rise is between 0.38 m (0.28–0.55 m, *likely range*) (SSP1-1.9) and 0.77 m (0.63–1.02 m, *likely range*) (SSP5-8.5) (Table 9.9). The methods, models and scenarios used for sea level projections in the AR6 are updated from those employed by the SROCC, with contributions informed by the latest model projections described in the ocean and cryosphere sections (TS.2.4 and TS.2.5). Despite these differences, the sea level projections are broadly consistent with those of the SROCC. {4.3.2, 9.6.3}

Importantly, *likely* range projections do not include those ice-sheet-related processes whose quantification is highly uncertain or that are characterized by deep uncertainty. Higher amounts of GMSL rise before 2100 could be caused by earlier-than-projected disintegration of marine ice shelves, the abrupt, widespread onset of Marine Ice Sheet Instability (MISI) and Marine Ice Cliff Instability (MICI) around Antarctica, and faster-than-projected changes in the surface mass balance and dynamical ice loss from Greenland (Box TS.4, Figure 1). In a low-likelihood, high-impact storyline and a high CO_2 emissions scenario, such processes could in combination contribute more than one additional meter of sea level rise by 2100. {Box TS.3, 4.3.2, 9.6.3, Box 9.4}

Beyond 2100, GMSL will continue to rise for centuries to millennia due to continuing deep ocean heat uptake and mass loss from ice sheets, and will remain elevated for thousands of years (*high confidence*). By 2150, considering only those processes in whose projections we have at least *medium confidence* and assuming no acceleration in ice-mass flux after 2100, GMSL is projected to rise between 0.6 m (0.4–0.9 m, *likely* range) (SSP1-1.9) and 1.4 m (1.0–1.9 m, *likely* range) (SSP5-8.5), relative to the period 1995–2014 based on the SSP scenario extensions. Under high CO_2 emissions, processes in which there is *low confidence*, such as Marine Ice Cliff Instability (MICI), could drive GMSL rise up to about 5 m by 2150 (Box TS.4, Figure 1a). By 2300, GMSL will rise 0.3–3.1 m under low CO_2 emissions (SSP1-2.6) (*low confidence*). Under high CO_2 emissions (SSP5-8.5), projected GMSL rise is between 1.7 and 6.8 m by 2300 in the absence of MICI and by up to 16 m considering MICI (*low confidence*). Over 2000 years, there is *medium agreemen*t and *limited evidence* that committed GMSL rise is projected to be about 2–3 m with 1.5°C peak warming, 2–6 m with 2°C of peak warming, 4–10 m with 3°C of peak warming, 12–16 m with 4°C of peak warming, and 19–22 m with 5°C of peak warming. {TS.1.3.1, 9.6.3}

Looking at uncertainty in time provides an alternative perspective on uncertainty in future sea-level rise (Box TS.4, Figure 1c). For example, considering only *medium confidence* processes, GMSL rise is likely to exceed 0.5 m between about 2080 and 2170 under SSP1-2.6 and between about 2070 and 2090 under SSP5-8.5. Given the long-term commitment, uncertainty in the timing of reaching different levels of GMSL rise is an important consideration for adaptation planning. {9.6.3}

At regional scales, additional processes come into play that modify the local sea level change relative to GMSL, including vertical land motion; ocean circulation and density changes and gravitational, rotational, and deformational effects arising from the redistribution of water and ice mass between land and the ocean. These processes give rise to a spatial pattern that tends to increase sea level rise at the low latitudes and reduce sea-level rise at high latitudes. However, over the 21st century, the majority of coastal locations have a median projected regional sea level rise within ± 20% of the projected GMSL change (*medium confidence*). Further details on regional sea level change and extremes are provided in TS.4. {9.6.3}

[START BOX TS.4, FIGURE 1 HERE]

Box TS.4, Figure 1: Global mean sea level change on different time scales and under different scenarios. (a) GMSL change from 1900 to 2150, observed (1900–2018) and projected under the SSP scenarios (2000–2150), relative to a 1995–2014 baseline. Solid lines show median projections. Shaded regions show *likely* ranges for SSP1-2.6 and SSP3-7.0. Dotted and dashed lines show respectively the 83rd and 95th percentile low-confidence projections for SSP5-8.5. Bars at right show *likely* ranges for SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 in 2150. Lightly shaded thick/thin bars show 17th–83rd/5th–95th percentile *low-confidence* ranges in 2150 for SSP1-2.6 and SSP5-8.5, based upon projection methods incorporating structured expert judgement

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and Marine Ice Cliff Instability. *Low-confidence* range for SSP5-8.5 in 2150 extends to 4.8/5.4 m at the 83rd/95th percentile. (b) GMSL change on 100- (blue), 2,000- (green) and 10,000-year (magenta) time scales as a function of global surface temperature, relative to 1850–1900. For 100-year projections, GMSL is projected for the year 2100, relative to a 1995-2014 baseline, and temperature anomalies are average values over 2081–2100. For longer-term commitments, warming is indexed by peak warming above 1850–1900 reached after cessation of emissions. Shaded regions show paleo-constraints on global surface temperature and GMSL for the Last Interglacial and mid-Pliocene Warm Period. Lightly shaded thick/thin blue bars show 17th–83rd/5th–95th percentile *low-confidence* ranges for SSP1-2.6 and SSP5-8.5 in 2100, plotted at 2°C and 5°C. (c) Timing of exceedance of GMSL thresholds of 0.5, 1.0, 1.5 and 2.0 m, under different SSPs. Lightly shaded thick/thin bars show 1th7–83rd/5th–95th percentile *low-confidence* ranges for SSP1-2.6 and SSP5-8.5.

[END BOX TS.4 HERE]

[START BOX TS.5 HERE]

Box TS.5: The Carbon Cycle

The continued growth of atmospheric CO_2 concentrations over the industrial era is unequivocally due to emissions from human activities. Ocean and land carbon sinks slow the rise of CO_2 in the atmosphere. Projections show that while land and ocean sinks absorb more CO_2 under high emissions scenarios than low emissions scenarios, the fraction of emissions removed from the atmosphere by natural sinks decreases with higher concentrations (*high confidence*). Projected ocean and land sinks show similar responses for a given scenario, but the land sink has a much higher inter-annual variability and wider model spread. The slowed growth rates of the carbon sinks projected for the second half of this century are linked to strengthening carbon–climate feedbacks and stabilization of atmospheric CO_2 under medium-to-no-mitigation and high-mitigation scenarios respectively. {5.2, 5.4}

Carbon sinks for anthropogenic CO_2 are associated with mainly physical ocean and biospheric land processes that drive the exchange of carbon between multiple land, ocean and atmospheric reservoirs. These exchanges are driven by increasing atmospheric CO_2, but modulated by changes in climate (Box TS.5, Figure 1 c,d). The Northern and Southern Hemispheres dominate the land and ocean sinks, respectively (Box TS.5, Figure 1). Ocean circulation and thermodynamic processes also play a critical role in coupling the global carbon and energy (heat) cycles. There is *high confidence* that this ocean carbon–heat nexus is an important basis for one of the most important carbon–climate metrics, the transient climate response to cumulative CO_2 emissions (TCRE) (TS.3.2.1) used to determine the remaining carbon budget. {5.1, 5.2, 5.5, 9.2, Cross-Chapter Box 5.3}

Based on multiple lines of evidence using interhemispheric gradients of CO_2 concentrations, isotopes, and inventory data, it is unequivocal that the growth in CO_2 in the atmosphere since 1750 (see TS.2.2) is due to the direct emissions from human activities. The combustion of fossil fuels and land-use change for the period 1750–2019 resulted in the release of 700 ± 75 PgC (*likely* range, 1 PgC = 10^{15} g of carbon) to the atmosphere, of which about 41% ± 11% remains in the atmosphere today (*high confidence*). Of the total anthropogenic CO_2 emissions, the combustion of fossil fuels was responsible for about 64% ± 15%, growing to an 86% ± 14% contribution over the past 10 years. The remainder resulted from land-use change. During the last decade (2010–2019), average annual anthropogenic CO_2 emissions reached the highest levels in human history at 10.9 ± 0.9 PgC yr^{-1} (*high confidence*). Of these emissions, 46% accumulated in the atmosphere (5.1 ± 0.02 PgC yr^{-1}), 23% (2.5 ± 0.6 PgC yr^{-1}) was taken up by the ocean and 31% (3.4 ± 0.9 PgC yr^{-1}) was removed by terrestrial ecosystems (*high confidence*). {5.2.1, 5.2.2, 5.2.3}

The ocean (*high confidence*) and land (*medium confidence*) sinks of CO_2 have increased with anthropogenic emissions over the past six decades (Box TS.5, Figure 1). This coherence between emissions and the growth

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in ocean and land sinks has resulted in the airborne fraction of anthropogenic CO_2 remaining at 44%±10% over the past 60 years (*high confidence*). Interannual and decadal variability of the ocean and land sinks indicate that they are sensitive to changes in the growth rate of emissions as well as climate variability, and therefore also sensitive to climate change (*high confidence*). {5.2.1}

The land CO_2 sink is driven by carbon uptake by vegetation, with large interannual variability, for example, linked to ENSO. Since the 1980s, carbon fertilization from rising atmospheric CO_2 has increased the strength of the net land CO_2 sink (*medium confidence*). During the historical period, the growth of the ocean sink has been primarily determined by the growth rate of atmospheric CO_2. However, there is *medium confidence* that changes to physical and chemical processes in the ocean and in the land biosphere, which govern carbon feedbacks, are already modifying the characteristics of variability, particularly the seasonal cycle of CO_2 in both the ocean and land. However, changes to the multi-decadal trends in the sinks have not yet been observed. {2.3.4, 3.6.1, 5.2.1, TS.2.3, TS.2.6}

In AR6, ESM projections are assessed with CO_2 concentrations by 2100 from about 400 ppm (SSP1-1.9) to above 1100 ppm (SSP5-8.5). Most simulations are performed with prescribed atmospheric CO_2 concentrations, which already account for a central estimate of climate–carbon feedback effects. CO_2 emissions-driven simulations account for uncertainty in these feedbacks, but do not significantly change the projected global surface temperature changes (*high confidence*). Although land and ocean sinks absorb more CO_2 under high emissions than low emissions scenarios, the fraction of emissions removed from the atmosphere decreases (*high confidence*). This means that the more CO_2 that is emitted, the less efficient the ocean and land sinks become (*high confidence*), an effect which compensates for the logarithmic relationship between CO_2 and its radiative forcing, which means that for each unit increase in additional atmospheric CO_2 the effect on global temperature decreases. (Box TS.5, Figure 1f,g). {4.3.1, 5.4.5, 5.5.1.2}

Ocean and land sinks show similar responses for a given scenario, but the land sink has a much higher inter-annual variability and wider model spread. Under SSP3-7.0 and SSP5-8.5, the initial growth of both sinks in response to increasing atmospheric concentrations of CO_2 is subsequently limited by emerging carbon–climate feedbacks (*high confidence*) (Box TS.5, Figure 1f). Projections show that the ocean and land sinks will stop growing from the second part of the 21st century under all emissions scenarios, but with different drivers for different emissions scenarios. Under SSP3-7.0 and SSP5-8.5, the weakening growth rate of the ocean CO_2 sink in the second half of the century is primarily linked to the strengthening positive feedback from reduced carbonate buffering capacity, ocean warming and altered ocean circulation (e.g., AMOC changes). In contrast, for SSP1-1.9, SSP1-2.6 and SSP2-4.5, the weakening growth rate of the ocean carbon sink is a response to the stabilizing or declining atmospheric CO_2 concentrations. Under high CO_2 emissions scenarios, it is *very likely* that the land carbon sink will grow more slowly due to warming and drying from the mid 21st century, but it is *very unlikely* that it will switch from being a sink to a source before 2100. Climate change alone is expected to increase land carbon accumulation in the high latitudes (not including permafrost, which is assessed in TS2.5 and TS.3.2.2), but also to lead to a counteracting loss of land carbon in the tropics (*medium confidence*). ESM projections show that the overall uncertainty of atmospheric CO_2 by 2100 is still dominated by the emission pathway, but carbon–climate feedbacks (see TS.3.3.2) are important, with increasing uncertainties in high emissions pathways (Box TS.5, Figure 1e). {4.3.2, 5.4.1, 5.4.2, 5.4.4, 5.4.5, 11.6, 11.9, Cross-Chapter Box 5.1, Cross-Chapter Box 5.3, TS.3.3.2}

Under three SSP scenarios with long-term extensions until 2300 (SSP5-8.5, SSP5-3.4-OS, SSP1-2.6), ESMs project a change of the land from a sink to a source (*medium confidence*). The scenarios make simplified assumptions about emissions reductions, with SSP1-2.6 and SSP5-3.4-OS reaching about 400 ppm by 2300, while SSP5-8.5 exceeds 2000 ppm. Under high emissions the transition is warming-driven, whereas it is linked to the decline in atmospheric CO_2 under net negative CO_2 emissions. The ocean remains a sink throughout the period to 2300 except under very large net negative emissions. The response of the natural aspects of the carbon cycle to carbon dioxide removal is further developed in TS.3.3.2. {5.4.9, TS.3.3.2; Figure Box TS.5f}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Box TS.5, Figure 1: Carbon cycle processes and projections. Carbon cycle response to forcings. The figure shows changes in carbon storage in response to elevated CO_2 (a, b) and the response to climate warming (c, d). Maps show spatial patterns of changes in carbon uptake during simulations with 1% per year increase in CO_2 {section 5.4.5.5}, and zonal mean plots show distribution of carbon changes is dominated by the land (green lines) in the tropics and northern hemisphere and ocean (blue lines) in the southern hemisphere. Hatching indicates regions where fewer than 80% of models agree on the sign of response. (e) Future CO_2 projections: projected CO_2 concentrations in the SSP scenarios in response to anthropogenic emissions, results from coupled ESMs for SSP5-8.5 and from the MAGICC7 emulator for other scenarios {section 4.3.1}. (f) Future carbon fluxes: projected combined land and ocean fluxes (positive downward) up to 2100 for the SSP scenarios, and extended to 2300 for available scenarios, 5-95% uncertainty plumes shown for SSP1-2.6 and SSP3-7.0 {section 5.4.5.4, 5.4.10}. The numbers near the top show the number of model simulations used. (g) Sink fraction: the fraction of cumulative emissions of CO_2 removed by land and ocean sinks. The sink fraction is smaller under conditions of higher emissions. {5.4.5, 5.5.1; Figure 5.27; Figure 4.31; Figure 5.25; Figure 5.30; Figure 5.31}

[END BOX TS.5, FIGURE 1 HERE]

[END BOX TS.5 HERE]

TS.2.6 Land Climate, Including Biosphere and Extremes

Land surface air temperatures have risen faster than the global surface temperature since the 1850s, and it is *virtually certain* that this differential warming will persist into the future. It is *virtually certain* that the frequency and intensity of hot extremes and the intensity and duration of heat waves have increased since 1950 and will further increase in the future even if global warming is stabilized at 1.5°C. The frequency and intensity of heavy precipitation events have increased over a majority of those land regions with good observational coverage (*high confidence*) and will *extremely likely* increase over most continents with additional global warming. Over the past half century, key aspects of the biosphere have changed in ways that are consistent with large-scale warming: climate zones have shifted poleward, and the growing season length in the Northern Hemisphere extratropics has increased (*high confidence*). The amplitude of the seasonal cycle of atmospheric CO_2 poleward of 45°N has increased since the 1960s (*very high confidence*), with increasing productivity of the land biosphere due to the increasing atmospheric CO_2 concentration as the main driver (*medium confidence*). Global-scale vegetation greenness has increased since the 1980s (*high confidence*). {2.3, 3.6, 4.3, 4.5, 5.2, 11.3, 11.4, 11.9, 12.4}

Observed temperatures over land have increased by 1.61 [1.34–1.83] °C between the period 1850–1900 and 2011–2020. Warming of the land is about 45% larger than for global surface temperature, and about 80% larger than warming of the ocean surface. Warming of the land surface during the period 1971–2018 contributed about 5% of the increase in the global energy inventory (TS.3.1), nearly twice the estimate in AR5 (*high confidence*). It is *virtually certain* that the average surface warming over land will continue to be higher than over the ocean throughout the 21st century. The warming pattern will *likely* vary seasonally, with northern high latitudes warming more during winter than summer (*medium confidence*). {2.3.1, 4.3.1, 4.5.1, Box 7.2, 7.2.2, Cross-Chapter Box 9.1, 11.3, Atlas 11.2}

The frequency and intensity of hot extremes (warm days and nights) and the intensity and duration of heatwaves have increased globally and in most regions since 1950, while the frequency and intensity of cold extremes have decreased (*virtually certain*). There is *high confidence* that the increases in frequency and severity of hot extremes are due to human-induced climate change. Some recent extreme events would have been *extremely unlikely* to occur without human influence on the climate system. It is *virtually certain* that the further changes in hot and cold extremes will occur throughout the 21st century in nearly all inhabited

ACCEPTED VERSION SUBJECT TO FINAL EDITING

regions, even if global warming is stabilized at 1.5°C (Table TS.2, Figure TS.12a). {1.3, Cross-Chapter Box 3.2, 11.1.4, 11.3.2, 11.3.4, 11.3.5, 11.9, 12.4}

Greater warming over land alters key water cycle characteristics (Box TS.6). The rate of change in mean precipitation and runoff, and their variability, increases with global warming (Figure TS.12e,f). The majority of the land area has experienced decreases in available water during dry seasons due to the overall increase in evapotranspiration (*medium confidence*). The land area affected by increasing drought frequency and severity will expand with increasing global warming (*high confidence*; Figure TS.12c). There is *low confidence* that the increase of plant water-use efficiency due to higher atmospheric CO_2 concentration alleviates extreme agricultural and ecological droughts in conditions characterized by limited soil moisture and increased atmospheric evaporative demand. {2.3.1, CCB 5.1, 8.2.3, 8.4.1, Box 11.1, 11.2.4, 11.4, 11.6}

Northern Hemisphere spring snow cover has decreased since at least 1978 (*very high confidence*), and there is *high confidence* that trends in snow cover loss extend back to 1950. It is *very likely* that human influence contributed to these reductions. Earlier onset of snowmelt has contributed to seasonally dependent changes in streamflow (*high confidence*). A further decrease of Northern Hemisphere seasonal snow cover extent is *virtually certain* under further global warming (Figure TS.12d). {2.3.2, 3.4.2, 8.3.2. 9.5.3, 12.4, Atlas 8.2, 9.2, 11.2}

The frequency and intensity of heavy precipitation events have increased over a majority of land regions with good observational coverage since 1950 (*high confidence*, Box TS.6, Table TS.2). Human influence is *likely* the main driver of this change (Table TS.2). It is *extremely likely* that on most continents heavy precipitation will become more frequent and more intense with additional global warming (Table TS.2, Figure TS.12 b). The projected increase in heavy precipitation extremes translates to an increase in the frequency and magnitude of pluvial floods (*high confidence*) (Table TS.2). {Cross-Chapter Box 3.2, 8.4.1, 11.4.2, 11.4.4, 11.5.5, 12.4}

The probability of compound extreme events has *likely* increased due to human-induced climate change. Concurrent heat waves and droughts have become more frequent over the last century, and this trend will continue with higher global warming (*high confidence*). The probability of compound flooding (storm surge, extreme rainfall and/or river flow) has increased in some locations, and will continue to increase due to both sea level rise and increases in heavy precipitation, including changes in precipitation intensity associated with tropical cyclones (*high confidence*). {11.8.1, 11.8.2, 11.8.3}

Changes in key aspects of the terrestrial biosphere, such as an increase of the growing season length in much of the Northern Hemisphere extratropics since the mid-20th century (*high confidence*), are consistent with large-scale warming. At the same time an increase in the amplitude of the seasonal cycle of atmospheric CO_2 beyond 45°N since the early 1960s (*high confidence*) and a global-scale increase in vegetation greenness of the terrestrial surface since the early 1980s (*high confidence*) have been observed. Increasing atmospheric CO_2, warming at high latitudes and land management interventions have contributed to the observed greening trend, but there is *low confidence* in their relative roles. There is *medium confidence* that increased plant growth associated with CO_2 fertilization is the main driver of the observed increase in amplitude of the seasonal cycle of atmospheric CO_2 in the Northern hemisphere. Reactive nitrogen, ozone and aerosols affect terrestrial vegetation and carbon cycle through deposition and effects on large-scale radiation (*high confidence*), but the magnitude of these effects on the land carbon sink, ecosystem productivity and indirect CO_2 forcing remains uncertain. {2.3.4, 3.6.1, 5.2.1, 6.4.5, 12.3.7, 12.4}

Over the last century, there has been a poleward and upslope shift in the distribution of many land species (*very high confidence*) as well as increases in species turnover within many ecosystems (*high confidence*). There is *high confidence* that the geographical distribution of climate zones has shifted in many parts of the world in the last half century. SRCCL concluded that continued warming will exacerbate desertification processes (*medium confidence*) and ecosystems will become increasingly exposed to climates beyond those that they are currently adapted to (*high confidence*). There is *medium confidence* that climate change will increase disturbance by, for example, fire and tree mortality across several ecosystems. Increases are projected in drought, aridity, and fire weather in some regions (TS.4.3; *high confidence*). There is *low*

ACCEPTED VERSION SUBJECT TO FINAL EDITING

confidence in the magnitude of these changes, but the probability of crossing uncertain regional thresholds (e.g., fires, forest dieback) increases with further warming (*high confidence*). The response of biogeochemical cycles to the anthropogenic perturbation can be abrupt at regional scales, and irreversible on decadal to century time scales (*high confidence*). {2.3.4, 5.4.3, 5.4.9, 11.6, 11.8, 12.5, SRCCL 2.2, SRCCL 2.5, SR1.5 3.4}

[START FIGURE TS.12 HERE]

Figure TS.12: Land-related changes relative to the 1850-1900 as a function of global warming levels. a) Changes in the frequency (left scale) and intensity (in °C, right scale) of daily hot extremes occurring every 10- and 50-years; b) as a), but for daily heavy precipitation extremes, with intensity change in %; c) Changes in 10-year droughts aggregated over drought-prone regions (CNA, NCA, SCA, NSA, SAM, SWS, SSA, MED, WSAF, ESAF, MDG, SAU, and EAU; for definitions of these regions, see Atlas.2), with drought intensity (right scale) represented by the change of annual mean soil moisture, normalized with respect to interannual variability; d) Changes in Northern Hemisphere spring (March-April-May) snow cover extent relative to 1850-1900; e,f) Relative change (%) in annual mean of total precipitable water (grey line), precipitation (red solid lines), runoff (blue solid lines) and in standard deviation (i.e. variability) of precipitation (red dashed lines) and runoff (blue dashed lines) averaged over (e) tropical and (f) extratropical land as function of global warming levels. CMIP6 models that reached a 5°C warming level in the 21st century in SSP5-8.5 above the 1850-1900 average have been used. Precipitation and runoff variability are estimated by respective standard deviation after removing linear trends. Error bars show the 17-83% confidence interval for the warmest +5°C global warming level. {Figures 11.6, 11.7, 11.12, 11.15, 11.18, 9.24, 8.16, Atlas.2}

[END FIGURE TS.12 HERE]

[START BOX TS.6 HERE]

Box TS.6: Water Cycle

Human-caused climate change has driven detectable changes in the global water cycle since the mid-20th century (*high confidence*), and it is projected to cause substantial further changes at both global and regional scales (*high confidence*). Global land precipitation has *likely* increased since 1950, with a faster increase since the 1980s (*medium confidence*). Atmospheric water vapour has increased throughout the troposphere since at least the 1980s (*likely*). Annual global land precipitation will increase over the 21st century as global surface temperature increases (*high confidence*). Human influence has been detected in amplified surface salinity and precipitation minus evaporation (P-E) patterns over the ocean (*high confidence*). The severity of very wet and very dry events increase in a warming climate (*high confidence*), but changes in atmospheric circulation patterns affect where and how often these extremes occur. Water cycle variability and related extremes are projected to increase faster than mean changes in most regions of the world and under all emission scenarios (*high confidence*). Over the 21st century, the total land area subject to drought will increase and droughts will become more frequent and severe (*high confidence*). Near-term projected changes in precipitation are uncertain mainly because of internal variability, model uncertainty and uncertainty in forcings from natural and anthropogenic aerosols (*medium confidence*). Over the 21st century and beyond, abrupt human-caused changes to the water cycle cannot be excluded (*medium confidence*). {2.3, 3.3, 4.3, 4.4, 4.5, 4.6, 8.2, 8.3, 8.4, 8.5, 8.6, 11.4, 11.6, 11.9}

There is *high confidence* that the global water cycle has intensified since at least 1980 expressed by, for example, increased atmospheric moisture fluxes and amplified precipitation minus evaporation patterns. Global land precipitation has *likely* increased since 1950, with a faster increase since the 1980s (*medium confidence*), and a *likely* human contribution to patterns of change, particularly for increases in high-latitude precipitation over the Northern Hemisphere. Increases in global mean precipitation are determined by a robust response to global surface temperature (*very likely* 2–3% per °C) that is partly offset by fast atmospheric adjustments to atmospheric heating by GHGs and aerosols (TS.3.2.2). The overall effect of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

anthropogenic aerosols is to reduce global precipitation through surface radiative cooling effects (*high confidence*). Over much of the 20th century, opposing effects of GHGs and aerosols on precipitation have been observed for some regional monsoons (*high confidence*) (Box TS.13). Global annual precipitation over land is projected to increase on average by 2.4% (–0.2% to 4.7% *likely* range) under SSP1-1.9, 4.6% (1.5% to 8.3% *likely* range) under SSP2-4.5, and 8.3% (0.9% to 12.9% *likely* range) under SSP5-8.5 by 2081–2100 relative to 1995–2014 (Box TS.6, Figure 1). Inter-model differences and internal variability contribute to a substantial range in projections of large-scale and regional water cycle changes (*high confidence*). The occurrence of volcanic eruptions can alter the water cycle for several years (*high confidence*). Projected patterns of precipitation change exhibit substantial regional differences and seasonal contrast as global surface temperature increases over the 21st century (Box TS.6, Figure 1). {2.3.1, 3.3.2, 3.3.3, 3.5.2, 4.3.1, 4.4.1, 4.5.1, 4.6.1, Cross-Chapter Box 4.1, 8.2.1, 8.2.2, 8.2.3, Box 8.1, 8.3.2.4, 8.4.1, 8.5.2, 10.4.2}

Global total column water vapour content has *very likely* increased since the 1980s, and it is *likely* that human influence has contributed to tropical upper tropospheric moistening. Near-surface specific humidity has increased over the ocean (*likely*) and land (*very likely*) since at least the 1970s, with a detectable human influence (*medium confidence*). Human influence has been detected in amplified surface salinity and precipitation minus evaporation (P-E) patterns over the ocean (*high confidence*). It is *virtually certain* that evaporation will increase over the ocean, and *very likely* that evapotranspiration will increase over land, with regional variations under future surface warming (Box TS.6, Figure 1). There is *high confidence* that projected increases in precipitation amount and intensity will be associated with increased runoff in northern high latitudes (Box TS.6, Figure 1). In response to cryosphere changes (TS.2.5), there have been changes in streamflow seasonality, including an earlier occurrence of peak streamflow in high-latitude and mountain catchments (*high confidence*). Projected runoff (Box TS.6, Figure 1c) is typically decreased by contributions from small glaciers because of glacier mass loss, while runoff from larger glaciers will generally increase with increasing global warming levels until their mass becomes depleted (*high confidence*). {2.3.1, 3.3.2, 3.3.3, 3.5.2, 8.2.3, 8.4.1, 11.5}

Warming over land drives an increase in atmospheric evaporative demand and in the severity of drought events (*high confidence*). Greater warming over land than over the ocean alters atmospheric circulation patterns and reduces continental near-surface relative humidity, which contributes to regional drying (*high confidence*). A *very likely* decrease in relative humidity has occurred over much of the global land area since 2000. Projected increases in evapotranspiration due to growing atmospheric water demand will decrease soil moisture (Box TS.6, Figure 1) over the Mediterranean region, southwestern North America, South Africa, southwestern South America and southwestern Australia (*high confidence*). Some tropical regions are also projected to experience enhanced aridity, including the Amazon basin and Central America (*high confidence*). The total land area subject to increasing drought frequency and severity will expand (*high confidence*), and in the Mediterranean, southwestern South America, and western North America, future aridification will far exceed the magnitude of change seen in the last millennium (*high confidence*). {4.5.1, 8.2.2, 8.2.3, 8.4.1, Box 8.2, 11.6, 11.9}

Land-use change and water extraction for irrigation have influenced local and regional responses in the water cycle (*high confidence*). Large-scale deforestation *likely* decreases evapotranspiration and precipitation and increases runoff over the deforested regions relative to the regional effects of climate change (*medium confidence*). Urbanization increases local precipitation (*medium confidence*) and runoff intensity (*high confidence*) (Box TS.14:). Increased precipitation intensities have enhanced groundwater recharge, most notably in tropical regions (*medium confidence*). There is *high confidence* that groundwater depletion has occurred since at least the start of the 21st century, as a consequence of groundwater withdrawals for irrigation in agricultural areas in drylands. {8.2.3, 8.3.1, 11.1.6, 11.4, 11.6, FAQ 8.1}

indicate the number of CMIP6 models used for estimating the ensemble mean. For other scenarios, please refer to relevant figures in Chapter 8. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. {8.4.1, Figures 8.14, 8.17, 8.18, 8.19}

[END BOX TS.6, FIGURE 1 HERE]

Water cycle variability and related extremes are projected to increase faster than mean changes in most regions of the world and under all emissions scenarios (*high confidence*). A warmer climate increases moisture transport into weather systems, which intensifies wet seasons and events (*high confidence*). The magnitudes of projected precipitation increases and related extreme events depend on model resolution and the representation of convective processes (*high confidence*). Increases in near-surface atmospheric moisture capacity of about 7% per 1ºC of warming lead to a similar response in the intensification of heavy precipitation from sub-daily up to seasonal time scales, increasing the severity of flood hazards (*high confidence*). The average and maximum rain-rates associated with tropical and extratropical cyclones, atmospheric rivers and severe convective storms will therefore also increase with future warming (*high confidence*). For some regions, there is *medium confidence* that peak tropical cyclone rain-rates will increase by more than 7% per 1°C of warming due to increased low-level moisture convergence caused by increases in wind intensity. In the tropics year-round and in the summer season elsewhere, interannual variability of precipitation and runoff over land is projected to increase at a faster rate than changes in seasonal mean precipitation (Figure TS.12e,f) (*medium confidence*). Sub-seasonal precipitation variability is also projected to increase with fewer rainy days but increased daily mean precipitation intensity over many land regions (*high confidence*). {4.5.3, 8.2.3, 8.4.1, 8.4.2, 8.5.1, 8.5.2, 11.4,11.5, 11.7, 11.9}

TS.3 Understanding the Climate System Response and Implications for Limiting Global Warming

This section summarizes advances in our knowledge of the Earth's energy budget, including the time evolution of forcings and climate feedbacks that lead to the climate system responses summarized in TS.2. It assesses advances since AR5 and SR1.5 in the estimation of remaining carbon budgets, the Earth system response to carbon dioxide removal and quantification of metrics that allow comparison of the relative effects of different forcing agents. The section also highlights future climate and air pollution responses due to projected changes in short-lived climate forcers (SLCFs), the state of understanding of the climate response to potential interventions related to solar radiation modification (SRM), and irreversibility, tipping points and abrupt changes in the climate system.

TS.3.1 Radiative Forcing and Energy Budget

Since AR5, the accumulation of energy in the Earth system, quantified by observations of warming of the ocean, atmosphere, land and melting of ice, has become established as a robust measure of the rate of global climate change on interannual-to-decadal time scales. Compared to changes in global surface temperature, the increase in the global energy inventory exhibits less variability, and thus better indicates underlying climate trends. The global energy inventory increased by 435 [325 to 545] Zettajoules (ZJ, equal to 10^{21} Joules) for the period 1971–2018 and 153 [100 to 206] ZJ for the period 2006–2018 (Figure TS.13), with more than 90% accounted for by ocean warming. To put these numbers in context, the 2006–2018 average Earth system heating is equivalent to approximately 20 times the rate of global energy consumption in 2018. The accumulation of energy is driven by a positive total anthropogenic effective radiative forcing (ERF) relative to 1750. The best estimate ERF of 2.72 W m^{-2} has increased by 0.43 Wm^{-2} relative to that given in AR5 (for 1750–2014) due to an increase in the greenhouse gas ERF that is partly compensated by a more negative aerosol ERF compared to AR5. The greenhouse gas ERF has been revised due to changes in atmospheric concentrations and updates to forcing efficiencies, while the revision to aerosol ERF is due to increased understanding of aerosol–cloud interactions and is supported by improved agreement between different lines of evidence. Improved quantification of ERF, the climate system radiative response and the observed energy increase in the Earth system for the period 1971–2018 demonstrate improved closure of the global energy budget (i.e., the extent to which the sum of the integrated forcing and the integrated radiative response equals the energy gain of the Earth system) compared to AR5. (*high confidence*) {7.2.2, Box 7.2, Table 7.1, 7.3.5, 7.5.2, FAQ7.1}

[START FIGURE TS.13 HERE]

Figure TS.13: Estimates of the net cumulative energy change (ZJ = 10^{21} Joules) for the period 1971–2018 associated with: (a) observations of changes in the Global Energy Inventory (b) Integrated Radiative Forcing; (c) Integrated Radiative Response. *The intent is to show assessed changes in energy budget and ERFs.* Black dotted lines indicate the central estimate with *likely* and *very likely* ranges as indicated in the legend. The grey dotted lines indicate the energy change associated with an estimated 1850-1900 Earth energy imbalance of 0.2 W m^{-2} (panel a) and an illustration of an assumed pattern effect of –0.5 W m^{-2}°C^{-1} (panel c). Background grey lines indicate equivalent heating rates in W m^{-2} per unit area of Earth's surface. Panels (d) and (e) show the breakdown of components, as indicated in the legend, for the Global Energy Inventory and Integrated Radiative Forcing, respectively. Panel (f) shows the Global Energy Budget assessed for the period 1971–2018, i.e. the consistency between the change in the Global Energy Inventory relative to 1850-1900 and the implied energy change from Integrated Radiative Forcing plus Integrated Radiative Response under a number of different assumptions, as indicated in the figure legend, including assumptions of correlated and uncorrelated uncertainties in Forcing plus Response. Shading represents the *very likely* range for observed energy change relative to 1850-1900 and *likely* range for all other quantities. Forcing and Response timeseries are expressed relative to a baseline period of 1850–1900. {Box 7.2 Figure 1}

[END FIGURE TS.13 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The global energy inventory change for the period 1971–2018 corresponds to an Earth energy imbalance (Box TS.1) of 0.57 [0.43 to 0.72] W m^{-2}, increasing to 0.79 [0.52 to 1.06] W m^{-2} for the period 2006–2018. Ocean heat uptake is by far the largest contribution and accounts for 91% of the total energy change. Land warming, melting of ice and warming of the atmosphere account for about 5%, 3% and 1% of the total change, respectively. More comprehensive analysis of inventory components, cross-validation of satellite and in situ-based estimates of the global energy imbalance and closure of the global sea level budget have led to a strengthened assessment relative to AR5. (*high confidence*) {Box 7.2, 7.2.2, Table 7.1, 7.5.2.3, Cross-Chapter Box 9.1, 9.6.1, Table 9.5}

As in AR5, the perturbations to the Earth's top-of-atmosphere energy budget are quantified using ERFs (also see TS.2.2). These include any consequent adjustments to the climate system (e.g., from changes in atmospheric temperatures, clouds, and water vapour as shown in Figure TS.14), but exclude any surface temperature response. Since the AR5, ERFs have been estimated for a larger number of forcing agents and shown to be more closely related to the temperature response than the stratospheric-temperature adjusted radiative forcing. (*high confidence*) {7.3.1}

[START FIGURE TS.14 HERE]

Figure TS.14: Schematic representation of changes in the top-of atmosphere (TOA) radiation budget following a perturbation. *The intent of the figure is to illustrate the concept of adjustments in the climate system following a perturbation in the radiation budget*. The baseline TOA energy budget (a) responds instantaneously to perturbations (b), leading to adjustments in the atmospheric meteorology and composition, and land surface that are independent of changes in surface temperature (c). Surface temperature changes (here using an increase as an example) lead to physical, biogeophysical and biogeochemical feedback processes (d). Long term feedback processes, such as those involving ice sheets, are not shown here. {adapted from Chapter 7 Figure 7.2, FAQ 7.2 Figure 1, and Figure 8.3}

[END FIGURE TS.14 HERE]

Improved quantification of ERF, the climate system radiative response, and the observed energy increase in the Earth system for the period 1971–2018, demonstrate improved closure of the global energy budget relative to AR5 (Figure TS.13). Combining the *likely* range of ERF over this period with the central estimate of radiative response gives an expected energy gain of 340 [47 to 662] ZJ. Both estimates are consistent with an independent observation-based assessment of the global energy increase of 284 [96 to 471] ZJ, (*very likely range*) expressed relative to the estimated 1850–1900 Earth energy imbalance. (*high confidence*) {7.2.2, Box 7.2, 7.3.5}

The assessed greenhouse gas ERF over the 1750–2019 period (TS.2.2) has increased by 0.59 W m^{-2} over AR5 estimates for 1750–2011. This increase includes +0.34 W m^{-2} from increases in atmospheric concentrations of well-mixed greenhouse gases (including halogenated species) since 2011, +0.15 W m^{-2} from upwards revisions of their radiative efficiencies and +0.10 W m^{-2} from re-evaluation of the ozone and stratospheric water vapour ERF. {7.3.2, 7.3.4, 7.3.5}

For CO_2, CH_4, N_2O, and chlorofluorocarbons, there is now evidence to quantify the effect on ERF of tropospheric adjustments. The assessed ERF for a doubling of CO_2 compared to 1750 levels (3.9 ± 0.5 Wm^{-2}) is larger than in AR5. For CO_2, the adjustments include the physiological effects on vegetation. The reactive well-mixed greenhouse gases (methane, nitrous oxide, and halocarbons) cause additional chemical adjustments to the atmosphere through changes in ozone and aerosols (Figure TS.15a). The ERF due to methane emissions is 1.21 [0.90 to 1.51] W m^{-2}, of which 0.33 [0.25 to 0.41] W m^{-2} is attributed to chemical adjustments mainly via ozone. These chemical adjustments also affect the emission metrics (Section TS.3.3.3). SO_2 emission changes make the dominant contribution to the ERF from aerosol–cloud interactions (*high confidence*). Over the 1750–2019 period, the contributions from the emitted compounds to global surface temperature changes broadly match their contributions to the ERF (*high confidence*) (Figure TS.15b). Since a peak in emissions-induced SO_2 ERF has already occurred recently (TS.2.2) and since there

ACCEPTED VERSION SUBJECT TO FINAL EDITING

is a delay in the full global surface temperature response owing to the thermal inertia in the climate system, changes in SO_2 emissions have a slightly larger contribution to global surface temperature change compared with changes in CO_2 emissions, relative to their respective contributions to ERF. {6.4.2, 7.3.2}

Aerosols contributed an ERF of –1.3 [–2.0 to –0.6] W m^{-2} over the period 1750 to 2014 (*medium confidence*). The ERF due to aerosol–cloud interactions (ERFaci) contributes most to the magnitude of the total aerosol ERF (*high confidence*), and is assessed to be –1.0 [–1.7 to –0.3] W m^{-2} (*medium confidence*), with the remainder due to aerosol–radiation interactions (ERFari), assessed to be –0.3 [–0.6 to 0.0] W m^{-2} (*medium confidence*). There has been an increase in the estimated magnitude – but a reduction in the uncertainty – of the total aerosol ERF relative to AR5, supported by a combination of increased process-understanding and progress in modelling and observational analyses (Figure TS.15c). Effective radiative forcing estimates from these separate lines of evidence are now consistent with each other, in contrast to AR5, and support the assessment that it is *virtually certain* that the total aerosol ERF is negative. Compared to AR5, the assessed magnitude of ERFaci has increased, while that of ERFari has decreased. {7.3.3, 7.3.5}

[START FIGURE TS.15 HERE]

Figure TS.15: Contribution to ERF and b) global surface temperature change from component emissions between 1750 to 2019 based on CMIP6 models and c) net aerosol effective radiative forcing (ERF) from different lines of evidence. *The intent of the figure is to show advances since AR5 in the understanding of a) aerosol ERF from different lines of evidence as assessed in Chapter 7, b) emissions-based ERF and c) global surface temperature response for SLCFs as estimated in Chapter 6.* In panel a), ERFs for well-mixed greenhouse gases (WMGHGs) are from the analytical formulae. ERFs for other components are multi-model means based on ESM simulations that quantify the effect of individual components. The derived emission-based ERFs are rescaled to match the concentration-based ERFs in Figure 7.6. Error bars are 5-95% and for the ERF account for uncertainty in radiative efficiencies and multi-model error in the means. In panel b), the global mean temperature response is calculated from the ERF time series using an impulse response function. In panel c), the AR6 assessment is based on energy balance constraints, observational evidence from satellite retrievals, and climate model-based evidence. For each line of evidence, the assessed best-estimate contributions from ERF due to ERFari and ERFaci are shown with darker and paler shading, respectively. Estimates from individual CMIP5 and CMIP6 models are depicted by blue and red crosses, respectively. The observational assessment for ERFari is taken from the instantaneous forcing due to aerosol-radiation interactions (IRFari). Uncertainty ranges are given in black bars for the total aerosol ERF and depict *very likely* ranges. {Sections 7.3.3, 6.4.2, Cross-Chapter Box 7.1, Figures 6.12, 7.5 ; Table 7.8}

[END FIGURE TS.15 HERE]

TS.3.2 Climate Sensitivity and Earth-System Feedbacks

TS.3.2.1 Equilibrium Climate Sensitivity, Transient Climate Response, and Transient Climate Response to Cumulative Carbon-dioxide Emissions

Since AR5, substantial quantitative progress has been made in combining new evidence of Earth's climate sensitivity, with improvements in the understanding and quantification of Earth's energy imbalance, the instrumental record of global surface temperature change, paleoclimate change from proxy records, climate feedbacks and their dependence on time scale and climate state. A key advance is the broad agreement across these multiple lines of evidence, supporting a best estimate of equilibrium climate sensitivity (ECS) of 3°C, with a *very likely* range of 2°C to 5°C. The *likely* range of 2.5°C to 4°C is narrower than the AR5 *likely* range of 1.5°C to 4.5°C. {7.4, 7.5}

Constraints on ECS and TCR (see Glossary) are based on four main lines of evidence: feedback process understanding, climate change and variability seen within the instrumental record, paleoclimate evidence, and so-called 'emergent constraints', whereby a relationship between an observable quantity and either ECS

ACCEPTED VERSION SUBJECT TO FINAL EDITING

or TCR established within an ensemble of models is combined with observations to derive a constraint on ECS or TCR. In reports up to and including the IPCC third assessment report, ECS and TCR derived directly from ESMs were the primary line of evidence. However, since AR4, historical warming and paleoclimates provided useful additional evidence (Figure TS.16a). AR6 differs from previous reports in not directly using climate model estimates of ECS and TCR in the assessed ranges of climate sensitivity. {1.5, 7.5}

It is now clear that when estimating ECS and TCR, the dependence of feedbacks on time scales and the climate state must be accounted for. Feedback processes are expected to become more positive overall (more amplifying of global surface temperature changes) on multi-decadal time scales as the spatial pattern of surface warming evolves and global surface temperature increases, leading to an ECS that is higher than was inferred in AR5 based on warming over the instrumental record (*high confidence*). Historical surface temperature change since 1870 has shown relatively little warming in several key regions of positive feedbacks, including the eastern equatorial Pacific Ocean and the Southern Ocean, while showing greater warming in key regions of negative feedbacks, including the western Pacific warm pool. Based on process understanding, climate modelling, and paleoclimate reconstructions of past warm periods, it is expected that future warming will become enhanced over the eastern Pacific Ocean (*medium confidence*) and Southern Ocean (*high confidence*) on centennial time scales. This new understanding, along with updated estimates of historical temperature change, ERF, and energy imbalance, reconciles previously disparate ECS estimates. {7.4.4, 7.5.2, 7.5.3,}

The AR6 best estimate of ECS is 3°C, the *likely* range is 2.5 to 4°C and the *very likely* range is 2 to 5°C. There is a high level of agreement among the four main lines of evidence listed above (Figure TS.16b), and altogether it is *virtually certain* that ECS is larger than 1.5°C, but currently it is not possible to rule out ECS values above 5°C. Therefore, the 5°C upper end of the *very likely* range is assessed with *medium confidence* and the other bounds with *high confidence*. {7.5.5}

Based on process understanding, warming over the instrumental record, and emergent constraints, the best estimate of TCR is 1.8°C, the *likely* range is 1.4° to 2.2°C and the *very likely* range is 1.2° to 2.4°C. There is a high level of agreement among the different lines of evidence (Figure TS.16c) (*high confidence*). {7.5.5}

On average, CMIP6 models have higher mean ECS and TCR values than the CMIP5 generation of models and also have higher mean values and wider spreads than the assessed best estimates and *very likely* ranges within this Report. These higher mean ECS and TCR values can, in some models, be traced to changes in extratropical cloud feedbacks (*medium confidence*). The broader ECS and TCR ranges from CMIP6 also lead the models to project a range of future warming that is wider than the assessed future warming range, which is based on multiple lines of evidence (Cross-Section Box TS.1). However, some of the high-sensitivity CMIP6 models (TS.1.2.2) are less consistent with observed recent changes in global warming and with paleoclimate proxy records than models with ECS within the *very likely* range. Similarly, some of the low-sensitivity models are less consistent with the paleoclimate data. The CMIP6 models with the highest ECS and TCRs values provide insights into low-likelihood, high-impact futures, which cannot be excluded based on currently available evidence (Cross-Section Box TS.1). {4.3.1, 4.3.4, 7.4.2, 7.5.6}

Uncertainties regarding the true value of ECS and TCR are the dominant source of uncertainty in global temperature projections over the 21st century under moderate to high GHG concentrations scenarios. For scenarios that reach net zero CO_2 emissions (TS.3.3), the uncertainty in the ERF values of aerosol and other SLCFs contribute substantial uncertainty in projected temperature. Global ocean heat uptake is a smaller source of uncertainty in centennial warming. {7.5.7}

[START FIGURE TS.16 HERE]

Figure TS.16: **a) Evolution of equilibrium climate sensitivity (ECS) assessments from the Charney Report through a succession of IPCC Assessment Reports to AR6, and lines of evidence and combined assessment for (b) ECS and (c) transient climate response (TCR) in AR6.** In panel (a), the lines of evidence considered are listed below each assessment. Best estimates are marked by horizontal bars,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

likely ranges by vertical bars, and very likely ranges by dotted vertical bars. In panel (b) and (c), assessed ranges are taken from Tables 7.13 and 7.14 for ECS and TCR respectively. Note that for the ECS assessment based on both the instrumental record and paleoclimates, limits (i.e., one-sided distributions) are given, which have twice the probability of being outside the maximum/minimum value at a given end, compared to ranges (i.e., two tailed distributions) which are given for the other lines of evidence. For example, the *extremely likely* limit of greater than 95% probability corresponds to one side of the *very likely* (5% to 95%) range. Best estimates are given as either a single number or by a range represented by grey box. CMIP6 ESM values are not directly used as a line of evidence but are presented on the Figure for comparison. {Sections 1.5, 7.5; Tables 7.13, 7.14; Figures 7.18}

[END FIGURE TS.16 HERE]

The transient climate response to cumulative CO_2 emissions (TCRE) is the ratio between globally averaged surface temperature increase and cumulative CO_2 emissions (see Glossary). This report reaffirms with *high confidence* the finding of AR5 that there is a near-linear relationship between cumulative CO_2 emissions and the increase in global average temperature caused by CO_2 over the course of this century for global warming levels up to at least 2°C relative to 1850–1900. The TCRE falls *likely* in the 1.0°C–2.3°C per 1000 PgC range, with a best estimate of 1.65°C per 1000 PgC. This range is about 15% narrower than the 0.8°–2.5°C per 1000 PgC assessment of the AR5 because of a better integration of evidence across chapters, in particular the assessment of TCR. Beyond this century, there is *low confidence* that the TCRE alone remains an accurate predictor of temperature changes in scenarios of very low or net negative CO_2 emissions because of uncertain Earth system feedbacks that can result in further changes in temperature or a path dependency of warming as a function of cumulative CO_2 emissions. {5.4, 5.5.1, 4.6.2}

TS.3.2.2 Earth System Feedbacks

The combined effect of all climate feedback processes is to amplify the climate response to forcing (*virtually certain*). While major advances in the understanding of cloud processes have increased the level of confidence and decreased the uncertainty range for the cloud feedback by about 50% compared to AR5, clouds remain the largest contribution to overall uncertainty in climate feedbacks (*high confidence*). Uncertainties in the ECS and other climate sensitivity metrics, such as the transient climate response (TCR) and the transient climate response to cumulative CO_2 emissions (TCRE), are the dominant source of uncertainty in global temperature projections over the 21st century under moderate to high GHG emissions scenarios. CMIP6 models have higher mean values and wider spreads in ECS and TCR than the assessed best estimates and *very likely* ranges within this Report, leading the models to project a range of future warming that is wider than the assessed future warming range (TS.2.2). {7.1, 7.4.2, 7.5}

Earth system feedbacks can be categorised into three broad groups: physical feedbacks, biogeophysical and biogeochemical feedbacks, and feedbacks associated with ice sheets. In previous assessments, the ECS has been associated with a distinct set of physical feedbacks (Planck response, water vapour, lapse rate, surface albedo, and cloud feedbacks). In this assessment, a more general definition of ECS is adopted whereby all biogeophysical and biogeochemical feedbacks that do not affect the atmospheric concentration of CO_2 are included. These include changes in natural methane emissions, natural aerosol emissions, nitrous oxide, ozone, and vegetation, which all act on time scales of years to decades and are therefore relevant for temperature change over the 21st century. Because the total biogeophysical and non-CO_2 biogeochemical feedback is assessed to have a central value that is near zero (*low confidence*), including it does not affect the assessed ECS but does contribute to the net feedback uncertainty. The biogeochemical feedbacks that affect the atmospheric concentration of CO_2 are not included because ECS is defined as the response to a sustained doubling of CO_2. Moreover, the long-term feedbacks associated with ice sheets are not included in the ECS owing to their long time scales of adjustment. {5.4, 6.4, 7.4, 7.5, Box 7.1}

The net effect of changes in clouds in response to global warming is to amplify human-induced warming, that is, the net cloud feedback is positive (*high confidence*). Compared to AR5, major advances in the understanding of cloud processes have increased the level of confidence and decreased the uncertainty range

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in the cloud feedback by about 50% (Figure TS.17a). An assessment of the low-altitude cloud feedback over the subtropical ocean, which was previously the major source of uncertainty in the net cloud feedback, is improved owing to a combined use of climate model simulations, satellite observations, and explicit simulations of clouds, altogether leading to strong evidence that this type of cloud amplifies global warming. The net cloud feedback is assessed to be +0.42 [–0.10 to 0.94] W m^{-2} °C^{-1}. A net negative cloud feedback is *very unlikely*. The CMIP5 and CMIP6 ranges of cloud feedback are similar to this assessed range, with CMIP6 having a slightly more positive median cloud feedback (*high confidence*). The surface albedo feedback and combined water vapour-lapse rate feedback are positive (Figure TS.17a), with *high confidence* in the estimated value of each based on multiple lines of evidence, including observations, models, and theory. {7.4.2, Figure 7.14, Table 7.10, Box TS.6}

Natural sources and sinks of non-CO_2 greenhouse gases such as methane (CH_4) and nitrous oxide (N_2O) respond both directly and indirectly to atmospheric CO_2 concentration and climate change, and thereby give rise to additional biogeochemical feedbacks in the climate system. Many of these feedbacks are only partially understood and are not yet fully included in ESMs. There is *medium confidence* that the net response of natural ocean and land CH_4 and N_2O sources to future warming will be increased emissions, but the magnitude and timing of the responses of each individual process is known with *low confidence*. {5.4.7}

Non-CO_2 biogeochemical feedbacks induced from changes in emissions, abundances or lifetimes of SLCFs mediated by natural processes or atmospheric chemistry are assessed to decrease ECS (Figure TS.17b). These non-CO_2 biogeochemical feedbacks are estimated from ESMs, which since AR5 have advanced to include a consistent representation of biogeochemical cycles and atmospheric chemistry. However, process-level understanding of many biogeochemical feedbacks involving SLCFs, particularly natural emissions, is still emerging, resulting in *low confidence* in the magnitude and sign of the feedbacks. The central estimate of the total biogeophysical and non-CO_2 biogeochemical feedback is assessed to be −0.01 [–0.27 to +0.25] W m^{-2} °C^{-1} (Figure TS.17a). {5.4.7, 5.4.8, 6.2.2, 6.4.5, 7.4, Table 7.10}

The combined effect of all known radiative feedbacks (physical, biogeophysical, and non-CO_2 biogeochemical) is to amplify the base climate response (in the absence of feedbacks), also known as the Planck temperature response[17] (*virtually certain*). Combining these feedbacks with the Planck response, the net climate feedback parameter is assessed to be –1.16 [–1.81 to –0.51] W m^{-2} °C^{-1}, which is slightly less negative than that inferred from the overall ECS assessment. The combined water vapour and lapse rate feedback makes the largest single contribution to global warming, whereas the cloud feedback remains the largest contribution to overall uncertainty. Due to the state-dependence of feedbacks, as evidenced from paleoclimate observations and from models, the net feedback parameter will increase (become less negative) as global temperature increases. Furthermore, on long time scales the ice sheet feedback parameter is *very likely* positive, promoting additional warming on millennial timescales as ice sheets come into equilibrium with the forcing. (*high confidence*) {7.4.2, 7.4.3, Figure 7.14, Table 7.10}

The carbon cycle provides for additional feedbacks on climate owing to the sensitivity of land–atmosphere and ocean–atmosphere carbon fluxes and storage to changes in climate and in atmospheric CO_2 (Figure TS.17c). Because of the time scales associated with land and ocean carbon uptake, these feedbacks are known to be scenario dependent. Feedback estimates deviate from linearity in scenarios of stabilizing or reducing concentrations. With *high confidence*, increased atmospheric CO_2 will lead to increased land and ocean carbon uptake, acting as a negative feedback on climate change. It is *likely* that a warmer climate will lead to reduced land and ocean carbon uptake, acting as a positive feedback. {4.3.2, 5.4.1-5, Box TS.4}

Thawing terrestrial permafrost will lead to carbon release (*high confidence*), but there is *low confidence* in the timing, magnitude and the relative roles of CO_2 versus CH_4 as feedback processes. An ensemble of models projects CO_2 release from permafrost to be 3–41 PgC per 1ºC of global warming by 2100, leading to warming strong enough that it must be included in estimates of the remaining carbon budget but weaker than the warming from fossil fuel burning. However, the incomplete representation of important processes, such

[17] For reference, the Planck temperature response for a doubling of atmospheric CO_2 is approximately 1.2°C at equilibrium.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

as abrupt thaw, combined with weak observational constraints, only allow *low confidence* in both the magnitude of these estimates and in how linearly proportional this feedback is to the amount of global warming. There is emerging evidence that permafrost thaw and thermokarst give rise to increased CH_4 and N_2O emissions, which leads to the combined radiative forcing from permafrost thaw being larger than from CO_2 emissions only. However, the quantitative understanding of these additional feedbacks is low, particularly for N_2O. These feedbacks, as well as potential additional carbon losses due to climate-induced fire feedback are not routinely included in Earth System models. {Box 5.1, 5.4.3, 5.4.7, 5.4.8, Box TS.9}

[START FIGURE TS.17 HERE]

Figure TS.17: An overview of physical and biogeochemical feedbacks in the climate system. *The intent is to summarize assessed estimates of physical, biogeophysical and biogeochemical feedbacks on global temperature based on Chapters 5, 6 and 7.* (a) Synthesis of physical, biogeophysical and non-CO_2 biogeochemical feedbacks that are included in the definition of ECS assessed in this Technical Summary. These feedbacks have been assessed using multiple lines of evidence including observations, models and theory. The net feedback is the sum of the Planck response, water vapour and lapse rate, surface albedo, cloud, and biogeophysical and non-CO_2 biogeochemical feedbacks. Bars denote the mean feedback values and uncertainties represent very likely ranges; (b) Estimated values of individual biogeophysical and non-CO_2 biogeochemical feedbacks. The atmospheric methane lifetime and other non-CO_2 biogeochemical feedbacks have been calculated using global Earth System Model simulations from AerChemMIP, while the CH_4 and N_2O source responses to climate have been assessed for the year 2100 using a range of modelling approaches using simplified radiative forcing equations. The estimates represent the mean and 5-95% range. The level of confidence in these estimates is *low* owing to the large model spread. (c) carbon-cycle feedbacks as simulated by models participating in the C4MIP of CMIP6. An independent estimate of the additional positive carbon-cycle climate feedbacks from permafrost thaw, which is not considered in most C4MIP models, is added. The estimates represent the mean and 5-95% range. Note that these feedbacks act through modifying the atmospheric concentration of CO_2 and thus are not included in the definition of ECS, which assumes a doubling of CO_2 but are included in the definition and assessed range of TCRE. {Sections Box 5.1, 5.4.7, 5.4.8, 6.4.5, 7.4.2, Figure 5.29, Tables 6.9, 7.10}

[END FIGURE TS.17 HERE]

TS.3.3 Temperature Stabilization, Net Zero Emissions and Mitigation

TS.3.3.1 Remaining Carbon Budgets and Temperature Stabilization

The near-linear relationship between cumulative CO_2 emissions and maximum global surface temperature increase caused by CO_2 implies that stabilizing human-induced global temperature increase at any level requires net anthropogenic CO_2 emissions to become zero. This near-linear relationship further implies that mitigation requirements for limiting warming to specific levels can be quantified in terms of a carbon budget (*high confidence*). Remaining carbon budget estimates have been updated since the AR5 with methodological improvements, resulting in larger estimates that are consistent with SR1.5. Several factors, including estimates of historical warming, future emissions from thawing permafrost, variations in projected non-CO_2 warming, and the global surface temperature change after cessation of CO_2 emissions, affect the exact value of carbon budgets (*high confidence*). {1.3.5, Box 1.2, 4.7.1, 5.5}

Limiting further climate change would require substantial and sustained reductions of GHG emissions. Without net zero CO_2 emissions, and a decrease in the net non-CO_2 forcing (or sufficient net negative CO_2 emissions to offset any further warming from net non-CO_2 forcing), the climate system will continue to warm. There is *high confidence* that mitigation requirements for limiting warming to specific levels over this century can be estimated using a carbon budget that relates cumulative CO_2 emissions to global mean temperature increase (Figure TS.18, Table TS.3). For the period 1850–2019, a total of 2390 ± 240 $GtCO_2$ of anthropogenic CO_2 has been emitted. Remaining carbon budgets (starting from 1 January 2020) for limiting

ACCEPTED VERSION SUBJECT TO FINAL EDITING

warming to 1.5°C, 1.7°C, and 2.0°C are estimated at 500 $GtCO_2$, 850 $GtCO_2$ and 1350 $GtCO_2$, respectively, based on the 50th percentile of TCRE. For the 67th percentile, the respective values are 400 $GtCO_2$, 700 $GtCO_2$ and 1150 $GtCO_2$. The remaining carbon budget estimates for different temperature limits assume that non-CO_2 emissions are mitigated consistent with the median reductions found in scenarios in the literature as assessed in SR1.5, but they may vary by an estimated ±220 $GtCO_2$ depending on how deeply future non-CO_2 emissions are assumed to be reduced (Table TS.3). {5.5.2, 5.6, Box 5.2, 7.6}

[START FIGURE TS.18 HERE]

Figure TS.18: Illustration of (a) relationship between cumulative emissions of CO_2 and global mean surface air temperature increase and (b) the assessment of the remaining carbon budget from its constituting components based on multiple lines of evidence. Carbon budgets consistent with various levels of additional warming are provided in Table 5.8 and should not be read from the illustrations in either panel. In panel (a) thin black line shows historical CO_2 emissions together with the assessed global surface temperature increase from 1850-1900 as assessed in Chapter 2 (Box 2.3). The orange-brown range with its central line shows the estimated human-induced share of historical warming. The vertical orange-brown line shows the assessed range of historical human-induced warming for the 2010–2019 period relative to 1850-1900 (Chapter 3). The grey cone shows the assessed *likely* range for the transient climate response to cumulative emissions of carbon dioxide (TCRE) (Section 5.5.1.4), starting from 2015. Thin coloured lines show CMIP6 simulations for the five scenarios of the WGI core set (SSP1-1.9, green; SSP1-2.6, blue; SSP2-4.5, yellow; SSP3-7.0, red; SSP5-8.5, maroon), starting from 2015 and until 2100. Diagnosed carbon emissions are complemented with estimated land-use change emissions for each respective scenario. Coloured areas show the Chapter 4 assessed *very likely* range of global surface temperature projections and thick coloured central lines the median estimate, for each respective scenario, relative to the original scenario emissions. For panel (b), the remaining allowable warming is estimated by combining the global warming limit of interest with the assessed historical human induced warming (Section 5.5.2.2.2), the assessed future potential non-CO_2 warming contribution (Section 5.5.2.2.3) and the ZEC (Section 5.5.2.2.4). The remaining allowable warming (vertical blue bar) is subsequently combined with the assessed TCRE (Section 5.5.1.4 and 5.5.2.2.1) and contribution of unrepresented Earth system feedbacks (Section 5.5.2.2.5) to provide an assessed estimate of the remaining carbon budget (horizontal blue bar, Table 5.8). Note that contributions in panel (b) are illustrative and are not to scale. For example, the central ZEC estimate was assessed to be zero. {Box 2.3; Sections 5.2.1, 5.2.2; Figure 5.31}

[END FIGURE TS.18 HERE]

[START TABLE TS.3 HERE]

Table TS.3: Estimates of remaining carbon budgets and their uncertainties. Assessed estimates are provided for additional human-induced warming, expressed as global surface temperature, since the recent past (2010–2019), which *likely* amounted to 0.8° to 1.3°C with a best estimate of 1.07°C relative to 1850–1900. Historical CO_2 emissions between 1850 and 2014 have been estimated at about 2180 ± 240 $GtCO_2$ (1-sigma range), while since 1 January 2015, an additional 210 $GtCO_2$ has been emitted until the end of 2019. $GtCO_2$ values to the nearest 50. {Table 5.8, Table 3.1, Table 5.1, Table 5.7, 5.5.1, 5.5.2, Box 5.2}

*(1) Human-induced global surface temperature increase between 1850–1900 and 2010–2019 is assessed at 0.8–1.3°C (*likely* range; Cross-Section Box TS.1) with a best estimate of 1.07°C. Combined with a central estimate of TCRE (1.65 °C EgC^{-1}) this uncertainty in isolation results in a potential variation of remaining carbon budgets of ±550 $GtCO_2$, which, however, is not independent of the assessed uncertainty of TCRE and thus not fully additional.

*(2) TCRE: transient climate response to cumulative emissions of carbon dioxide, assessed to fall *likely* between 1.0–2.3°C EgC^{-1} with a normal distribution, from which the percentiles are taken. Additional Earth system feedbacks are included in the remaining carbon budget estimates as discussed in Section 5.5.2.2.5.

*(3) Estimates assume that non-CO_2 emissions are mitigated consistent with the median reductions found in scenarios in the literature as assessed in SR1.5. Non-CO_2 scenario variations indicate how much remaining carbon budget estimates vary due to different scenario assumptions related to the future evolution of non-CO_2 emissions in mitigation scenarios from SR1.5 that reach net zero CO_2 emissions. This variation is additional to the uncertainty in TCRE. The WGIII Contribution to AR6 will reassess the potential for non-CO_2 mitigation based on literature since the SR1.5.

*(4) Geophysical uncertainties reported in these columns and TCRE uncertainty are not statistically independent, as uncertainty in TCRE depends on uncertainty in the assessment of historical temperature, non-CO_2 versus CO_2 forcing and uncertainty in emissions estimates. These estimates cannot be formally combined and these uncertainty variations are not directly additional to the spread of remaining carbon budgets due to TCRE uncertainty reported in columns 3 to 7.

*(5) Recent emissions uncertainty reflects the ±10% uncertainty in the historical CO_2 emissions estimate since 1 January 2015.

[END TABLE TS.3 HERE]

There is *high confidence* that several factors, including estimates of historical warming, future emissions from thawing permafrost, and variations in projected non-CO_2 warming, affect the value of carbon budgets but do not change the conclusion that global CO_2 emissions would need to decline to net zero to halt global warming. Estimates may vary by ±220 $GtCO_2$ depending on the level of non-CO_2 emissions at the time global anthropogenic CO_2 emissions reach net zero levels. This variation is referred to as non-CO_2 scenario uncertainty and will be further assessed in the AR6 Working Group III Contribution. Geophysical uncertainties surrounding the climate response to these non-CO_2 emissions result in an additional uncertainty of at least ±220 $GtCO_2$, and uncertainties in the level of historical warming result in a ±550 $GtCO_2$ uncertainty. {5.4, 5.5.2}

Methodological improvements and new evidence result in updated remaining carbon budget estimates. The assessment in AR6 applies the same methodological improvements as in SR1.5, which uses a recent observed baseline for historic temperature change and cumulative emissions. Changes compared to SR1.5 are therefore small: the assessment of new evidence results in updated median remaining carbon budget estimates for limiting warming to 1.5°C and 2°C being the same and about 60 $GtCO_2$ smaller, respectively, after accounting for emissions since SR1.5. Meanwhile, remaining carbon budgets for limiting warming to 1.5°C would be about 300–350 $GtCO_2$ larger if evidence and methods available at the time of the AR5 would be used. If a specific remaining carbon budget is exceeded, this results in a lower probability of keeping warming below a specified temperature level and higher irreversible global warming over decades to centuries, or alternatively a need for net negative CO_2 emissions or further reductions in non-CO_2 greenhouse gases after net zero CO_2 is achieved to return warming to lower levels in the long term. {5.5.2, 5.6, Box 5.2}

Based on idealized model simulations that explore the climate response once CO_2 emissions have been brought to zero, the magnitude of the zero CO_2 emissions commitment (ZEC, see Glossary) is assessed to be

ACCEPTED VERSION SUBJECT TO FINAL EDITING

likely smaller than 0.3°C for time scales of about half a century and cumulative CO_2 emissions broadly consistent with global warming of 2°C. However, there is *low confidence* about its sign on time scales of about half a century. For lower cumulative CO_2 emissions, the range would be smaller yet with equal uncertainty about the sign. If the ZEC is positive on decadal time scales, additional warming leads to a reduction in the estimates of remaining carbon budgets, and vice versa if it is negative. {4.7.1, 5.5.2}

Permafrost thaw is included in estimates together with other feedbacks that are often not captured by models. Limitations in modelling studies combined with weak observational constraints only allow *low confidence* in the magnitude of these estimates (TS.3.2.2). Despite the large uncertainties surrounding the quantification of the effect of additional Earth system feedback processes, such as emissions from wetlands and permafrost thaw, these feedbacks represent identified additional risk factors that scale with additional warming and mostly increase the challenge of limiting warming to specific temperature levels. These uncertainties do not change the basic conclusion that global CO_2 emissions would need to decline to net zero to halt global warming. {Box 5.1, 5.4.8, 5.5.2}

TS.3.3.2 Carbon Dioxide Removal

Deliberate carbon dioxide removal (CDR) from the atmosphere has the potential to compensate for residual CO_2 emissions to reach net zero CO_2 emissions or to generate net negative CO_2 emissions. In the same way that part of current anthropogenic net CO_2 emissions are taken up by land and ocean carbon stores, net CO_2 removal will be partially counteracted by CO_2 release from these stores (*very high confidence*). Asymmetry in the carbon cycle response to simultaneous CO_2 emissions and removals implies that a larger amount of CO_2 would need to be removed to compensate for an emission of a given magnitude to attain the same change in atmospheric CO_2 (*medium confidence*). CDR methods have wide-ranging side-effects that can either weaken or strengthen the carbon sequestration and cooling potential of these methods and affect the achievement of sustainable development goals (*high confidence*). {4.6.3, 5.6}

Carbon dioxide removal (CDR) refers to anthropogenic activities that deliberately remove CO_2 from the atmosphere and durably store it in geological, terrestrial or ocean reservoirs, or in products. Carbon dioxide is removed from the atmosphere by enhancing biological or geochemical carbon sinks or by direct capture of CO_2 from air. Emission pathways that limit global warming to 1.5°C or 2°C typically assume the use of CDR approaches in combination with GHG emissions reductions. CDR approaches could be used to compensate for residual emissions from sectors that are difficult or costly to decarbonize. CDR could also be implemented at a large scale to generate global net negative CO_2 emissions (i.e., anthropogenic CO_2 removals exceeding anthropogenic emissions), which could compensate for earlier emissions as a way to meet long-term climate stabilization goals after a temperature overshoot. This Report assesses the effects of CDR on the carbon cycle and climate. Co-benefits and trade-offs for biodiversity, water and food production are briefly discussed for completeness, but a comprehensive assessment of the ecological and socio-economic dimensions of CDR options is left to the WGII and WGIII reports. {4.6.3, 5.6}

CDR methods have the potential to sequester CO_2 from the atmosphere (*high confidence*). In the same way part of current anthropogenic net CO_2 emissions are taken up by land and ocean carbon stores, net CO_2 removal will be partially counteracted by CO_2 release from these stores, such that the amount of CO_2 sequestered by CDR will not result in an equivalent drop in atmospheric CO_2 (*very high confidence*). The fraction of CO_2 removed from the atmosphere that is not replaced by CO_2 released from carbon stores, a measure of CDR effectiveness, decreases slightly with increasing amounts of removal (*medium confidence*) and decreases strongly if CDR is applied at lower atmospheric CO_2 concentrations (*medium confidence*). The reduction in global surface temperature is approximately linearly related to cumulative CO_2 removal (*high confidence*). Because of this near-linear relationship, the amount of cooling per unit CO_2 removed is approximately independent of the rate and amount of removal (*medium confidence*). {4.6.3, 5.6.2.1, Figure 5.32, Figure 5.34}

Due to non-linearities in the climate system, the century-scale climate–carbon cycle response to a CO_2 removal from the atmosphere is not always equal and opposite to its response to a simultaneous CO_2 emission (*medium* confidence). For CO_2 emissions of 100 PgC released from a pre-industrial from a state in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

equilibrium with pre-industrial atmospheric CO_2 levels, CMIP6 models simulate that 27± 6% (mean ± 1 standard deviation) of emissions remain in the atmosphere 80–100 years after the emissions, whereas for removals of 100 PgC only 23 ± 6% of removals remain out of the atmosphere. This asymmetry implies that an extra amount of CDR is required to compensate for a positive emission of a given magnitude to attain the same change in atmospheric CO_2. Due to *limited agreement* between models, there is *low confidence* in the sign of the asymmetry of the temperature response to CO_2 emissions and removals. {4.6.3, 5.6.2.1, Figure 5.35}

Simulations with ESMs indicate that under scenarios where CO_2 emissions gradually decline, reach net zero and become net negative during the 21st century (e.g., SSP1–2.6), land and ocean carbon sinks begin to weaken in response to declining atmospheric CO_2 concentrations, and the land sink eventually turns into a source (Figure TS.19). This sink-to-source transition occurs decades to a few centuries after CO_2 emissions become net negative. The ocean remains a sink of CO_2 for centuries after emissions become net negative. Under scenarios with large net negative CO_2 emissions (e.g., SSP5–3.4–OS) and rapidly declining CO_2 concentrations, the land source is larger than for SSP1–2.6 and the ocean also switches to a source. While the general response is robust across models, there is *low confidence* in the timing of the sink-to-source transition and the magnitude of the CO_2 source in scenarios with net negative CO_2 emissions. Carbon dioxide removal could reverse some aspects climate change if CO_2 emissions become net negative, but some changes would continue in their current direction for decades to millennia. For instance, sea level rise due to ocean thermal expansion would not reverse for several centuries to millennia (*high confidence*) (Box TS.4). {4.6.3, 5.4.10, 5.6.2.1, Figure 5.30, Figure 5.33}

[START FIGURE TS.19 HERE]

Figure TS.19: Carbon sink response in a scenario with net CO_2 removal from the atmosphere. *The intent of this figure is to show how atmospheric CO_2 evolves under negative emissions and its dependence on the negative emissions technologies. It also shows the evolution of the ocean and land sinks.* Shown are CO_2 flux components from concentration-driven Earth system model simulations during different emission stages of SSP1–2.6 and its long-term extension. (a) Large net positive CO_2 emissions, (b) small net positive CO_2 emissions, (c) – (d) net negative CO_2 emissions, (e) net zero CO_2 emissions. Positive flux components act to raise the atmospheric CO_2 concentration, whereas negative components act to lower the CO_2 concentration. Net CO_2 emissions, land and ocean CO_2 fluxes represent the multi-model mean and standard deviation (error bar) of four ESMs (CanESM5, UKESM1, CESM2-WACCM, IPSL-CM6a-LR) and one EMIC (UVic ESCM). Net CO_2 emissions are calculated from concentration-driven Earth system model simulations as the residual from the rate of increase in atmospheric CO_2 and land and ocean CO_2 fluxes. Fluxes are accumulated over each 50-year period and converted to concentration units (ppm). {5.6.2.1, Figure 5.33}

[END FIGURE TS.19 HERE]

CDR methods have a range of side effects that can either weaken or strengthen the carbon sequestration and cooling potential of these methods and affect the achievement of sustainable development goals (*high confidence*). Biophysical and biogeochemical side-effects of CDR methods are associated with changes in surface albedo, the water cycle, emissions of CH_4 and N_2O, ocean acidification and marine ecosystem productivity (*high confidence*). These side-effects and associated Earth system feedbacks can decrease carbon uptake and/or change local and regional climate and in turn limit the CO_2 sequestration and cooling potential of specific CDR methods (*medium confidence*). Deployment of CDR, particularly on land, can also affect water quality and quantity, food production and biodiversity (*high confidence*). These effects are often highly dependent on local context, management regime, prior land use, and scale (*high confidence*). The largest co-benefits are obtained with methods that seek to restore natural ecosystems or improve soil carbon sequestration (*medium confidence*). The climate and biogeochemical effects of terminating CDR are expected to be small for most CDR methods (*medium confidence*). {4.6.3, 5.6.2.2, 8.4.3, 8.6.3, Figure 5.36}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

TS.3.3.3 Relating Different Forcing Agents

When including other GHGs, the choice of emission metric affects the quantification of net zero GHG emissions and their resulting temperature outcome (*high confidence*). Reaching and sustaining net zero GHG emissions typically leads to a peak and decline in temperatures when quantified with the global warming potential over a 100-year period (GWP-100). Carbon-cycle responses are more robustly accounted for in emission metrics compared to AR5 (*high confidence*). New emission metric approaches can be used to generate equivalent cumulative emissions of CO_2 for short-lived greenhouse gases based on their rate of emissions. {7.6.2}

Over 10- to 20-year time scales, the temperature response to a single year's worth of current emissions of SLCFs is at least as large as that of CO_2, but because the effect of SLCFs decays rapidly over the first few decades after emission, the net long-term temperature response to a single year's worth of emissions is predominantly determined by cumulative CO_2 emissions. Emission reductions in 2020 associated with COVID-19 containment led to small and positive global ERF; however, global and regional climate responses to the forcing are undetectable above internal variability due to the temporary nature of emission reductions. {6.6, Cross-Chapter Box 6.1}

The relative climate effects of different forcing agents are typically quantified using emission metrics that compare the effects of an idealised pulse of 1 kg of some climate forcing agent against a reference climate forcing agent, almost always CO_2. The two most prominent pulse emissions metrics are the global warming potential (GWP) and global temperature change potential (GTP) (see Glossary). The climate responses to CO_2 emissions by convention include the effects of warming on the carbon cycle, so for consistency these need to be determined also for non-CO_2 emissions. The methodology for doing this has been placed on a more robust scientific footing compared to AR5 (*high confidence*). Methane from fossil fuel sources has slightly higher emission metric values than those from biogenic sources since it leads to additional fossil CO_2 in the atmosphere (*high confidence*). Updates to the chemical adjustments for methane and nitrous oxide emissions (Section TS.3.1) and revisions in their lifetimes result in emission metrics for GWP and GTP that are slightly lower than in AR5 (*medium confidence*). Emission metrics for the entire suite of GHGs assessed in the AR6 have been calculated for various time horizons. {7.6.1, Table 7.15, Table 7.SM.7}

New emission metric approaches, such as GWP* and Combined-GTP (CGTP), relate changes in the emission rate of short-lived greenhouse gases to equivalent cumulative emissions of CO_2 (cumulative CO_2-e emissions). Global surface temperature response from aggregated emissions of short-lived greenhouse gases over time is determined by multiplying these cumulative CO_2-e by TCRE (see TS.3.2.1). When GHGs are aggregated using standard metrics such as GWP or GTP, cumulative CO_2-e emissions are not necessarily proportional to future global surface temperature outcomes (*high confidence*) {Box 7.3, 7.6.1}

Emission metrics are needed to aggregate baskets of gases to determine net zero GHG emissions. Generally, achieving net zero CO_2 emissions and declining non-CO_2 radiative forcing would halt human-induced warming. Reaching net zero GHG emissions quantified by GWP-100 typically leads to declining temperatures after net zero GHGs emissions are achieved if the basket includes short-lived gases, such as methane. Net zero GHG emissions defined by CGTP or GWP* imply net zero CO_2 and other long-lived GHG emissions and constant (CGTP) or gradually declining (GWP*) emissions of short-lived gases. The warming evolution resulting from net zero GHG emissions defined in this way corresponds approximately to reaching net zero CO_2 emissions, and would thus not lead to declining temperatures after net zero GHG emissions are achieved but to an approximate temperature stabilization (*high confidence*). The choice of emission metric hence affects the quantification of net zero GHG emissions, and therefore the resulting temperature outcome of reaching and sustaining net zero GHG emissions levels (*high confidence*). {7.6.1.4, 7.6.2, 7.6.3}

As pointed out in AR5, ultimately, it is a matter for policymakers to decide which emission metric is most applicable to their needs. This Report does not recommend the use of any specific emission metric as the most appropriate metric depends on the policy goal and context (see Chapter 7, Section 7.6). A detailed

ACCEPTED VERSION SUBJECT TO FINAL EDITING

assessment of GHG metrics to support climate change mitigation and associated policy contexts is provided in the WGIII contribution to the AR6.

The global surface temperature response following a climate change mitigation measure that affects emissions of both short- and long-lived climate forcers depends on their lifetimes, their ERFs, how fast and for how long the emissions are reduced, and the thermal inertia in the climate system. Mitigation, relying on emission reductions and implemented through new legislation or technology standards, implies that emissions reductions occur year after year. Global temperature response to a year's worth of current emissions from different sectors informs about the mitigation potential (Figure TS.20). Over 10- to 20-year time scales, the influence of SLCFs is at least as large as that of CO_2, with sectors producing the largest warming being fossil fuel production and distribution, agriculture, and waste management. Because the effect of the SLCFs decays rapidly over the first few decades after emission, the net long-term temperature effect from a single year's worth of current emissions is predominantly determined by CO_2. Fossil fuel combustion for energy, industry and land transportation are the largest contributing sectors on a 100-year time scale (*high confidence*). Current emissions of CO_2, N_2O and SLCFs from East Asia and North America are the largest regional contributors to additional net future warming on both short (*medium confidence*) and long time scales (10 and 100 year) (*high confidence*). {6.6.1, 6.6.2, Figure 6.16}

COVID-19 restrictions led to detectable reductions in global anthropogenic NO_x (about 35% in April 2020) and fossil CO_2 (7%, with estimates ranging from 5.8% to 13.0%) emissions, driven largely by reduced emissions from the transportation sector (*medium confidence*). There is *high confidence* that, with the exception of surface ozone, reductions in pollutant precursors contributed to temporarily improved air quality in most regions of the world. However, these reductions were lower than that would be expected from sustained implementation of policies addressing air quality and climate change (*medium confidence*). Overall, the net global ERF from COVID-19 containment was likely small and positive for 2020 (with a temporary peak value less than 0.2 W m^{-2}), thus temporarily adding to the total anthropogenic climate influence, with positive forcing (warming influence) from aerosol changes dominating over negative forcings (cooling influence) from CO_2, NO_x and contrail cirrus changes. Consistent with this small net radiative forcing, and against a large component of internal variability, Earth system models show no detectable effect on global or regional surface temperature or precipitation (*high confidence*). {Cross Chapter Box 6.1}

[START FIGURE TS.20 HERE]

Figure TS.20: Global surface temperature change 10 and 100 years after a one-year pulse of present-day emissions. *This figure shows the sectoral contribution to present-day climate change by specific climate forcers including CO_2 as well as SLCFs.* The temperature response is broken down by individual species and shown for total anthropogenic emissions (top), and sectoral emissions on 10-year (left) and 100-year time scales (right). Sectors are sorted by (high-to-low) net temperature effect on the 10-year time scale. Error bars in the top panel show the 5-95% range in net temperature effect due to uncertainty in radiative forcing only (calculated using a Monte Carlo approach and best estimate uncertainties from the literature). Emissions for 2014 are from the CMIP6 emissions dataset, except for HFCs and aviation H_2O which rely on other datasets (see Section 6.6.2 for more details). CO_2 emissions are excluded from open biomass burning and residential biofuel use. {6.6.2, Figure 6.16}

[START BOX TS.7 HERE]

Box TS.7: Climate and Air Quality Responses to Short-lived Climate Forcers in Shared Socioeconomic Pathways

Future changes in emissions of short-lived climate forcers (SLCFs) are expected to cause an additional global mean warming with a large diversity in the end-of-century response across the WGI core set of SSPs, depending upon the level of climate change and air pollution mitigation. This additional warming is either due to reductions in cooling aerosols for air pollution regulation or due to increases in methane, ozone and HFCs. This additional warming is stable after 2040 in SSPs associated with lower global air pollution as long as methane emissions are also mitigated, but the overall warming induced by SLCF changes is higher in scenarios in which air quality continues to deteriorate (induced by growing fossil fuel use and limited air pollution control) (*high confidence*). Sustained methane mitigation reduces global surface ozone, contributing to air quality improvements and also reduces surface temperature in the longer term, but only sustained CO_2 emission reductions allow long-term climate stabilization (*high confidence*). Future changes in air quality (near-surface ozone and particulate matter, or PM) at global and local scales are predominantly driven by changes in ozone and aerosol precursor emissions rather than climate (*high confidence*). Air quality improvements driven by rapid decarbonization strategies, as in SSP1-1.9 and SSP1-2.6, are not sufficient in the near term to achieve air quality guidelines set by the World Health Organization in some highly polluted regions (*high confidence*). Additional policies (e.g., access to clean energy, waste management) envisaged to attain United Nations Sustainable Development Goals bring complementary SLCF reduction. {4,4,4, 6.6.3, 6.7.3, BOX TS.7 Figure 1, Box 6.2}

The net effect of SLCF emissions changes on temperature will depend on how emissions of warming and cooling SLCFs will evolve in the future. The magnitude of the cooling effect of aerosols remains the largest uncertainty in the effect of SLCFs in future climate projections. Since the SLCFs have undergone large changes over the past two decades, the temperature and air pollution responses are estimated relative to year 2019 instead of 1995–2014.

Temperature Response

In the next two decades, it is *very likely* that SLCF emission changes will cause a warming relative to 2019, across the WGI core set of SSPs (see TS.1.3.1), in addition to the warming from long-lived GHGs. The net effect of SLFC and HFC changes in global surface temperature across the SSPs is a *likely* warming of 0.06°C–0.35°C in 2040 relative to 2019. This near-term global mean warming linked to SLCFs is quite similar in magnitude across the SSPs due to competing effects of warming (methane, ozone) and cooling (aerosols) forcers (Box TS.7, Figure 1). There is greater diversity in the end-of-century response among the scenarios. SLCF changes in scenarios with no climate change mitigation (SSP3-7.0 and SSP5-8.5) will cause a warming in the *likely* range of 0.4°C–0.9°C in 2100 relative to 2019 due to increases in methane, tropospheric ozone and HFC levels. For the stringent climate change and pollution mitigation scenarios (SSP1-1.9 and SSP1-2.6), the cooling from reductions in methane, ozone and HFCs partially balances the warming from reduced aerosols, primarily sulphate, and the overall SLCF effect is a *likely* increase in global surface temperature of 0.0°C–0.3°C in 2100, relative to 2019. With intermediate climate change and air pollution mitigations, SLCFs in SSP2-4.5 add a *likely* warming of 0.2°C–0.5°C to global surface temperature change in 2100, with the largest warming resulting from reductions in aerosols. {4.4.4, 6.7.3}

Assuming implementation and efficient enforcement of both the Kigali Amendment to the Montreal Protocol on Ozone Depleting Substances and current national plans limit emissions (as in SSP1-2.6), the effects of HFCs on global surface temperature, relative to 2019, would remain below +0. 02°C from 2050 onwards versus about +0.04°C–0.08°C in 2050 and +0.1°C–0.3°C in 2100 considering only national HFC regulations decided prior to the Kigali Amendment (as in SSP5-8.5) (*medium confidence*). {6.6.3, 6.7.3}

Air Quality Responses

Air pollution projections range from strong reductions in global surface ozone and PM (e.g., SSP1-2.6, with stringent mitigation of both air pollution and climate change) to no improvement and even degradation (e.g.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

SSP3-7.0 without climate change mitigation and with only weak air pollution control) (*high confidence*). Under the SSP3-7.0 scenario, PM levels are projected to increase until 2050 over large parts of Asia, and surface ozone pollution is projected to worsen over all continental areas through 2100 (*high confidence*). In SSP5-8.5, a scenario without climate change mitigation but with stringent air pollution control, PM levels decline through 2100, but high methane levels hamper the decline in global surface ozone at least until 2080 (*high confidence*). {6.7.1}

[START BOX TS.7, FIGURE 1 HERE]

Box TS.7, Figure 1: Effects of short-lived climate forcers (SLCFs) on global surface temperature and air pollution across the WGI core set of Shared Socio-Economic Pathways (SSPs). *The intent of this figure is to show the climate and air quality (surface ozone and $PM_{2.5}$) response to SLCFs in the SSP scenarios for near and long-term.* Effects of net aerosols, tropospheric ozone, hydrofluorocarbons (HFCs) (with lifetimes less than 50 years), and methane are compared with those of total anthropogenic forcing for 2040 and 2100 relative to year 2019. The global surface temperature changes are based on historical and future evolution of Effective Radiative Forcing (ERF) as assessed in chapter 7 of this report. The temperature responses to the ERFs are calculated with a common impulse response function (R_T) for the climate response, consistent with the metric calculations in Chapter 7 (Box 7.1). The R_T has an equilibrium climate sensitivity of 3.0°C for a doubling of atmospheric CO_2 concentration (feedback parameter of -1.31 W m^{-2} $°C^{-1}$). The scenario total (grey bar) includes all anthropogenic forcings (long- and short-lived climate forcers, and land use changes). Uncertainties are 5-95% ranges. The global changes in air pollutant concentrations (ozone and $PM_{2.5}$) are based on multimodel CMIP6 simulations and represent changes in 5-year mean surface continental concentrations for 2040 and 2098 relative to 2019. Uncertainty bars represent inter-model ±1 standard deviation. {6.7.2, 6.7.3, Figure 6.24}

[END BOX TS.7, FIGURE 1 HERE]

[END BOX TS.7 HERE]

[START BOX TS.8 HERE]

Box TS.8: Earth System Response to Solar Radiation Modification

Since AR5, further modelling work has been conducted on aerosol-based solar radiation modification (SRM) options such as stratospheric aerosol injection, marine cloud brightening, and cirrus cloud thinning[18] and their climate and biogeochemical effects. These investigations have consistently shown that SRM could offset some of the effects of increasing GHGs on global and regional climate, including the carbon and water cycles (*high confidence*). However, there would be substantial residual or overcompensating climate change at the regional scales and seasonal time scales (*high confidence*), and large uncertainties associated with aerosol–cloud–radiation interactions persist. The cooling caused by SRM would increase the global land and ocean CO_2 sinks (*medium confidence*), but this would not stop CO_2 from increasing in the atmosphere or affect the resulting ocean acidification under continued anthropogenic emissions (*high confidence*). It is *likely* that abrupt water cycle changes will occur if SRM techniques are implemented rapidly. A sudden and sustained termination of SRM in a high CO_2 emissions scenario would cause rapid climate change (*high confidence*). However, a gradual phase-out of SRM combined with emission reduction and CDR would avoid these termination effects *(medium confidence*). {4.6.3, 5.6.3. 6.4.6, 8.6.3}.

Solar radiation modification (SRM) refers to deliberate large-scale climate intervention options that are studied as potential supplements to deep mitigation, for example, in scenarios that overshoot climate stabilization goals. SRM options aim to offset some of the warming effects of GHG emissions by

[18] Although cirrus cloud thinning aims to cool the planet by increasing longwave emissions to space, it is included in the portfolio of SRM options for consistency with AR5 and SR1.5. {4.6.3.3}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

modification of the Earth's shortwave radiation budget. Following SR1.5, the SRM assessed in this report also includes some options, such as cirrus cloud thinning, that alter the longwave radiation budget. SRM contrasts with climate change mitigation activities, such as emission reductions and CDR, as it introduces a 'mask' to the climate change problem by altering the Earth's radiation budget, rather than attempting to address the root cause of the problem, which is the increase in GHGs in the atmosphere. By masking only the climate effects of GHG emissions, SRM does not address other issues related to atmospheric CO_2 increase, such as ocean acidification. The WGI report assesses physical understanding of the Earth system response to proposed SRM and is based primarily on idealized climate model simulations. There are important other considerations, such as risk to human and natural systems, perceptions, ethics, cost, governance, and trans-boundary issues and their relationship to the United Nations Sustainable Development Goals—issues that the WGII (Chapter 16) and WGIII (Chapter 14) reports address. {4.6.3}

SRM options include those that increase surface albedo, brighten marine clouds by increasing the amount of cloud condensation nuclei, or reduce the optical depth of cirrus clouds by seeding them with ice nucleating particles. However, the most commonly studied approaches attempt to mimic the cooling effects of major volcanic eruptions by injecting reflective aerosols (e.g., sulphates) or their precursors (e.g., sulphur dioxide) into the stratosphere. {4.6.3, 5.6.3, 6.4.6}

SRM could offset some effects of greenhouse gas-induced warming on global and regional climate, but there would be substantial residual and overcompensating climate change at the regional scale and seasonal time scales (*high confidence*). Since the AR5, more modelling work has been conducted with more sophisticated treatment of aerosol-based SRM approaches, but the uncertainties in cloud–aerosol–radiation interactions are still large (*high confidence*). Modelling studies suggest that it is possible to stabilize multiple large-scale temperature indicators simultaneously by tailoring the deployment strategy of SRM options (*medium confidence*) but with large residual or overcompensating regional and seasonal climate changes. {4.6.3}

SRM approaches targeting shortwave radiation are *likely* to reduce global mean precipitation, relative to future CO_2 emissions scenarios, if all global mean warming is offset. In contrast, cirrus cloud thinning, targeting longwave radiation, is expected to cause an increase in global mean precipitation (*medium confidence*). If shortwave approaches are used to offset global mean warming, the magnitude of reduction in regional precipitation minus evapotranspiration (P-E) (Box TS.5), which is more relevant to freshwater availability, is smaller than precipitation decrease because of simultaneous reductions in both precipitation and evapotranspiration (*medium confidence*). {4.6.3, 8.2.1, 8.6.3}.

If SRM is used to cool the planet, it would cause a reduction in plant and soil respiration and slow the reduction of ocean carbon uptake due to warming (*medium confidence*). The result would be an enhancement of the global land and ocean CO_2 sinks (*medium confidence*) and a slight reduction in atmospheric CO_2 concentration relative to unmitigated climate change. However, SRM would not stop CO_2 from increasing in the atmosphere or affect the resulting ocean acidification under continued anthropogenic emissions (*high confidence*). {5.6.3}

The effect of stratospheric aerosol injection on global temperature and precipitation is projected by models to be detectable after one to two decades, which is similar to the time scale for the emergence of the benefits of emissions reductions. A sudden and sustained termination of SRM in a high GHG emissions scenario would cause rapid climate change and a reversal of the SRM effects on the carbon sinks (*high confidence*). It is also *likely* that a termination of strong SRM would drive abrupt changes in the water cycle globally and regionally, especially in the tropical regions by shifting the ITCZ and Hadley cells. At the regional scale, non-linear responses cannot be excluded, due to changes in evapotranspiration. However, a gradual phase-out of SRM combined with emissions reductions and CDR would avoid larger rates of changes (*medium confidence*). {4.6.3, 5.6.3, 8.6.3}.

[END BOX TS.8 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[START BOX TS.9 HERE]

Box TS.9: Irreversibility, Tipping Points and Abrupt Changes

The present rate of response of many aspects of the climate system are proportionate to the rate of recent temperature change, but some aspects may respond disproportionately. Some climate system components are slow to respond, such as the deep ocean overturning circulation and the ice sheets. It is *virtually certain* that irreversible, committed change is already underway for the slow-to-respond processes as they come into adjustment for past and present emissions. The paleoclimate record indicates that tipping elements exist in the climate system where processes undergo sudden shifts toward a different sensitivity to forcing, such as during a major deglaciation, where one degree of temperature change might correspond to a large or small ice sheet mass loss during different stages. For global climate indicators, evidence for abrupt change is limited, but deep ocean warming, acidification and sea level rise are committed to ongoing change for millennia after global surface temperatures initially stabilize and are irreversible on human time scales (*very high confidence*). At the regional scale, abrupt responses, tipping points and even reversals in the direction of change cannot be excluded (*high confidence*). Some regional abrupt changes and tipping points could have severe local impacts, such as unprecedented weather, extreme temperatures and increased frequency of droughts and forest fires. Models that exhibit such tipping points are characterised by abrupt changes once the threshold is crossed, and even a return to pre-threshold surface temperatures or to atmospheric carbon dioxide concentrations, does not guarantee that the tipping elements return to their pre-threshold state. Monitoring and early warning systems are being put into place to observe tipping elements in the climate system. {Box TS.2, Box TS.4, TS 3.3.2, 1.3, 1.4.4, 1.5, 4.3.2, Table 4.10, 5.3.4, 5.4.9, 7.5.3, 9.2.2, 9.2.4, 9.4.1, 9.4.2, 9.6.3, Cross-chapter Box 12.1}

Understanding of multi-decadal reversibility (i.e., the system returns to the previous climate state within multiple decades after the radiative forcing is removed) has improved since AR5 for many atmospheric, land surface and sea ice climate metrics following sea surface temperature recovery. Some processes suspected of having tipping points, such as the Atlantic Meridional Overturning Circulation (AMOC), have been found to often undergo recovery after temperature stabilization with a time delay (*low confidence*). However, substantial irreversibility is further substantiated for some cryosphere changes, ocean warming, sea level rise, and ocean acidification. {4.7.2, 5.3.3, 5.4.9, 9.2.2, 9.2.4, 9.4.1, 9.4.2, 9.6.3}

Some climate system components are slow to respond, such as the deep ocean overturning circulation and the ice sheets. It is *likely* that under stabilization of global warming at 1.5°C, 2.0°C, or 3.0°C relative to 1850–1900, the AMOC will continue to weaken for several decades by about 15%, 20% and 30% of its strength and then recover to pre-decline values over several centuries (*medium confidence*). At sustained warming levels between 2°C and 3°C, there is limited evidence that the Greenland and West Antarctic Ice Sheets will be lost almost completely and irreversibly over multiple millennia; both the probability of their complete loss and the rate of mass loss increases with higher surface temperatures (*high confidence*). At sustained warming levels between 3°C and 5°C, near-complete loss of the Greenland Ice Sheet and complete loss of the West Antarctic Ice Sheet is projected to occur irreversibly over multiple millennia (*medium confidence*); with substantial parts or all of Wilkes Subglacial Basin in East Antarctica lost over multiple millennia (*low confidence*). Early-warning signals of accelerated sea-level-rise from Antarctica, could possibly be observed within the next few decades. For other hazards (e.g., ice sheet behaviour, glacier mass loss and global mean sea level change, coastal floods, coastal erosion, air pollution, and ocean acidification) the time and/or scenario dimensions remain critical, and a simple and robust relationship with global warming level cannot be established (*high confidence*). {4.3.2, 4.7.2, 5.4.3, 5.4.5, 5.4.8, 8.6, 9.2, 9.4, Box 9.3, Cross-Chapter Box 12.1}

For global climate indicators, evidence for abrupt change is limited. For global warming up to 2°C above 1850-1900 levels, paleoclimate records do not indicate abrupt changes in the carbon cycle (*low confidence*). Despite the wide range of model responses, uncertainty in atmospheric CO_2 by 2100 is dominated by future anthropogenic emissions rather than uncertainties related to carbon-climate feedbacks (*high confidence*). There is no evidence of abrupt change in climate projections of global temperature for the next century: there is a near-linear relationship between cumulative CO_2 emissions and maximum global mean surface air

ACCEPTED VERSION SUBJECT TO FINAL EDITING

temperature increase caused by CO_2 over the course of this century for global warming levels up to at least 2°C relative to 1850-1900. The increase in global ocean heat content (TS2.4) will likely continue until at least 2300 even for low-emission scenarios, and global mean sea level rise will continue to rise for centuries to millennia following cessation of emissions (Box TS.4) due to continuing deep ocean heat uptake and mass loss of the Greenland and Antarctic Ice Sheets (*high confidence*). {2.2.3; Cross-Chapter Box 2.1; 5.1.1; 5.4; Cross-Chapter Box 5.1; Figures 5.3, 5.4, 5.25, 5.26; 9.2.2; 9.2.4}

The response of biogeochemical cycles to anthropogenic perturbations can be abrupt at regional scales and irreversible on decadal to century time scales (*high confidence*). The probability of crossing uncertain regional thresholds increases with climate change (*high confidence*). It is *very unlikely* that gas clathrates (mostly methane) in deeper terrestrial permafrost and subsea clathrates will lead to a detectable departure from the emissions trajectory during this century. Possible abrupt changes and tipping points in biogeochemical cycles lead to additional uncertainty in 21st century atmospheric GHG concentrations, but future anthropogenic emissions remain the dominant uncertainty (*high confidence*). There is potential for abrupt water cycle changes in some high-emission scenarios, but there is no overall consistency regarding the magnitude and timing of such changes. Positive land surface feedbacks, including vegetation, dust, and snow, can contribute to abrupt changes in aridity, but there is only *low confidence* that such changes will occur during the 21st century. Continued Amazon deforestation, combined with a warming climate, raises the probability that this ecosystem will cross a tipping point into a dry state during the 21st century (*low confidence*). {TS3.2.2, 5.4.3, 5.4.5, 5.4.8, 5.4.9, 8.6.2, 8.6.3, Cross-chapter Box 12.1}

[END BOX TS.9 HERE]

TS.4 Regional Climate Change

This section focuses on how to generate regional climate change information and its relevance for climate services; the drivers of regional climate variability and change, and how they are being affected by anthropogenic factors; and observed, attributed and projected changes in climate, including extreme events and climatic impact-drivers (CID), across all regions of the world. There is a small set of CID changes common to all land or ocean regions and a specific set of changes from a broader range of CIDs seen in each region. This regional diversity results from regional climate being determined by a complex interplay between the seasonal-to-multidecadal variation of large-scale modes of climate variability, external natural and anthropogenic forcings, local climate processes and related feedbacks.

TS.4.1 Generation and Communication of Regional Climate Change Information

Climate change information at regional scale is generated using a range of data sources and methodologies. Multi-model ensembles and models with a range of resolutions are important data sources, and discarding models that fundamentally misrepresent relevant processes improves the credibility of ensemble information related to these processes. A key methodology is distillation, combining lines of evidence and accounting for stakeholder context and values, which helps ensure the information is relevant, useful and trusted for decision making (see Core Concepts Box) (*high confidence*). Since the AR5, physical climate storylines have emerged as a complementary approach to ensemble projections to generate more accessible climate information and promote a more comprehensive treatment of risk. They have been used as part of the distillation process within climate services to generate the required context-relevant, credible and trusted climate information. Since AR5, climate change information produced for climate services has increased significantly due to scientific and technological advancements and growing user awareness, requirements, and demand (*very high confidence*). The decision-making context, level of user engagement and co-production between scientists, practitioners and users are important determinants of the type of climate service developed and its utility in supporting adaptation, mitigation and risk management decisions. {Box TS.1, 10.3, Cross-Chapter Box 10.3, 10.6, 12.6, Cross-chapter Box 12.2, Box TS.3}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

TS.4.1.1 Sources and Methodologies for Generating Regional Climate Information

Climate change information at regional scale is generated using a range of data sources and methodologies (TS.1.4). Understanding observed regional climate change and variability is based on the availability and analysis of multiple observational datasets that are suitable for evaluating the phenomena of interest (e.g., extreme events), including accounting for observational uncertainty. These datasets are combined with climate model simulations of observed changes and events to attribute causes of those changes and events to large- and regional-scale anthropogenic and natural drivers and to assess the performance of the models. Future simulations with many climate models (multi-model ensembles) are then used to generate and quantify ranges of projected regional climate responses. Discarding models that fundamentally misrepresent relevant processes improves the credibility of regional climate information generated from these ensembles (*high confidence*). However, multi-model mean and ensemble spread are not a full measure of the range of projection uncertainty and are not sufficient to characterize low-likelihood, high-impact changes (Box TS.3) or situations where different models simulate substantially different or even opposite changes (*high confidence*). Large single-model ensembles are now available and provide a more comprehensive spectrum of possible changes associated with internal variability (*high confidence*). {1.5.1, 1.5.4, 10.2, 10.3.3, 10.3.4, 10.4.1, 10.6.2, 11.2, Box 11.2, Cross-chapter Box 11.1, 12.4, Atlas.1.4.1, TS.1.2.1, TS.1.2.3, TS.4.2}

Depending on the region of interest, representing regionally important forcings (e.g., aerosols, land-use change and ozone concentrations) and feedbacks (e.g., between snow and albedo, soil-moisture and temperature, soil-moisture and precipitation) in climate models is a prerequisite for them to reproduce past regional trends to underpin the reliability of future projections (*medium confidence*). In some cases, even the sign of a projected change in regional climate cannot be trusted if relevant regional processes are not represented, for example, for variables such as precipitation and wind speed (*medium confidence*). In some regions, either geographical (e.g., Central Africa, Antarctica) or typological (e.g., mountainous areas, Small Islands and cities), and for certain phenomena, fewer observational records are available or accessible, which limits the assessment of regional climate change in these cases. {1.5.1, 1.5.3, 1.5.4, 8.5.1, 10.2, 10.3.3, 10.4.1, 11.1.6, 11.2, 12.4, Atlas.8.3, Atlas.11.1.5, Cross-Chapter Box Atlas.2, TS.1.2.2}

Methodologies such as statistical downscaling, bias adjustment and weather generators are beneficial as an interface between climate model projections and impact modelling and for deriving user-relevant indicators (*high confidence*). However, the performance of these techniques depends on that of the driving climate model: in particular, bias adjustment cannot overcome all consequences of unresolved or strongly misrepresented physical processes such as large-scale circulation biases or local feedbacks (*medium confidence*). {10.3.3, Cross-Chapter Box 10.2, 12.2, Atlas.2.2}

[START BOX TS.10 HERE]

Box TS.10: Event Attribution

The attribution of observed changes in extremes to human influence (including greenhouse gas and aerosol emissions and land-use changes) has substantially advanced since AR5, in particular for extreme precipitation, droughts, tropical cyclones, and compound extremes (*high confidence*). There is limited evidence for windstorms and convective storms. Some recent hot extreme events would have been *extremely unlikely* to occur without human influence on the climate system. (TS.1) {Cross-Working Group Box: Attribution, 11.2, 11.3, 11.4, 11.6, 11.7, 11.8}

Since AR5, the attribution of extreme weather events has emerged as a growing field of climate research with an increasing body of literature. It provides evidence that greenhouse gases and other external forcings have affected individual extreme weather events by disentangling anthropogenic drivers from natural variability. Event attribution is now an important line of evidence for assessing changes in extremes on regional scales. {Cross-Working Group Box: Attribution, TS.1, 11.1.4}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The regional extremes and events that have been studied are geographically uneven. A few events, for example, extreme rainfall events in the UK, heat waves in Australia, or Hurricane Harvey that hit Texas in 2017, have been heavily studied. Many highly impactful extreme weather events have not been studied in the event attribution framework, particularly in the developing world where studies are generally lacking. This is due to various reasons, including lack of observational data, lack of reliable climate models, and lack of scientific capacity. While the events that have been studied are not representative of all extreme events that have occurred, and results from these studies may also be subject to selection bias, the large number of event attribution studies provide evidence that changes in the properties of these local and individual events are in line with expected consequences of human influence on the climate and can be attributed to external drivers. {Cross-Working Group Box: Attribution, TS.4.1, 11.1.4, 11.2.2}

It is *very likely* that human influence is the main contributor to the observed increase in the intensity and frequency of hot extremes and the observed decrease in the intensity and frequency of cold extremes on continental scales. Some specific recent hot extreme events would have been *extremely unlikely* to occur without human influence on the climate system. Changes in aerosol concentrations have *likely* slowed the increase in hot extremes in some regions in particular from 1950–1980. No-till farming, irrigation, and crop expansion have similarly attenuated increases in summer hot extremes in some regions, such as central North America (*medium confidence*). {11.3.4}

Human influence has contributed to the intensification of heavy precipitation in three continents where observational data are most abundant, including North America, Europe and Asia (*high confidence*). On regional scales, evidence of human influence on extreme precipitation is limited, but new evidence from attributing individual heavy precipitation events found that human influence was a significant driver of the events. {11.4.4}

There is *low confidence* that human influence has affected trends in meteorological droughts in most regions, but *medium confidence* that they have contributed to the severity of some specific events. There is *medium confidence* that human-induced climate change has contributed to increasing trends in the probability or intensity of recent agricultural and ecological droughts, leading to an increase of the affected land area. {11.6.4}

Event attribution studies of specific strong tropical cyclones provide limited evidence for anthropogenic effects on tropical cyclone intensifications so far, but *high confidence* for increases in precipitation. There is *high confidence* that anthropogenic climate change contributed to extreme rainfall amounts during Hurricane Harvey (2017) and other intense tropical cyclones. {11.7.3}

The number of evident attribution studies on compound events is limited. There is *medium confidence* that weather conditions that promote wildfires have become more probable in southern Europe, northern Eurasia, the USA, and Australia over the last century. In Australia a number of event attribution studies show that there is *medium confidence* of increase in fire weather conditions due to human influence. {11.8.3, 12.4.3.2}

[START BOX TS.10, FIGURE 1 HERE]

Box TS.10, Figure 1: Synthesis of assessed observed changes and human influence of hot extremes (panel a), heavy precipitation (panel b) and agricultural and ecological drought (panel c) for the IPCC AR6 regions (displayed as hexagons). The colours in each panel represent the four outcomes of the assessment on the observed changes: In Panel a): red – at least *medium confidence* in an observed increase in hot extremes; blue – at least *medium confidence* in an observed decrease in hot extremes; white – no significant change in hot extremes is observed for the region as a whole; grey – the evidence in this region is insufficient (because of a lack of data and/or literature) to make an assessment for the region as a whole. In panel b): green – at least *medium confidence* in an observed increase in heavy rainfall; yellow - at least *medium confidence* in an observed decrease in heavy rainfall; white – no significant change in heavy rainfall is observed for the region as a whole; grey – the evidence in this region is insufficient

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(because of a lack of data and/or literature) to make an assessment for the region as a whole. In panel c): yellow – at least *medium confidence* in an observed increase in agricultural and ecological drought; green - at least *medium confidence* in an observed decrease in agricultural and ecological drought; white – no significant change in agricultural and ecological drought is observed for the region as a whole; grey – the evidence in this region is insufficient (because of a lack of data and/or literature) to make an assessment for the region as a whole. Each panel represents in addition the synthesis of assessment of the human influence on the observed changes based on available trend detection and attribution and event attribution scientific publications. The level of confidence is indicated by a number of dots: *high confidence* (three dots), *medium confidence* (two dots), *low confidence* (one dot), and when no assessment is possible, due to insufficient evidence for the specific region (horizontal bar). For hot extremes, the evidence is mostly drawn from changes in metrics based on daily maximum temperatures, regional studies using other metrics (heatwave duration, frequency and intensity) are used in addition {11.9.2}. For heavy precipitation, the evidence is mostly drawn from changes in metrics based on one-day or five-day precipitation amounts using global and regional studies {11.9.3}. Agricultural and ecological droughts are assessed based on observed and projected changes in total column soil moisture, complemented by evidence on changes in surface soil moisture, water-balance (precipitation minus evapotranspiration) and metrics driven by precipitation and atmospheric evaporative demand. {11.9.3} All assessments are made for each AR6 region as a whole and for the timeframe from 1950 to present thus, more local or assessment made on shorter time scales might differ from what is shown in the figure. {11.9, Table TS.5}.

[END BOX TS.10 HERE]

TS.4.1.2 Regional Climate Information Distillation and Climate Services

The construction of regional climate information involves people with a variety of backgrounds, from various disciplines, who have different sets of experiences, capabilities and values. The process of synthesizing climate information from different lines of evidence from a number of sources, taking into account the context of a user vulnerable to climate variability and change and the values of all relevant actors, is called distillation. Distillation is conditioned by the sources available, the actors involved and the context, which all depend heavily on the regions considered, and framed by the question being addressed. Distilling regional climate information from multiple lines of evidence and taking the user context into account increases fitness, usefulness, relevance and trust in that information for use in climate services (Box TS.11) and decision-making (*high confidence*). {1.2.3, 10.1.4, 10.5, Cross-Chapter Box 10.3, 12.6}

The distillation process can vary substantially, as it needs to consider multiple lines of evidence on all physically plausible outcomes (especially when they are contrasting) relevant to a specific decision required in response to a changing climate. Confidence in the distilled regional climate information is enhanced when there is agreement across multiple lines of evidence, so the outcome can be limited if these are inconsistent or contradictory. For example, in the Mediterranean region the agreement between different lines of evidence such as observations, projections by regional and global models, and understanding of the underlying mechanisms provides *high confidence* in summer warming that exceeds the global average (see Box TS.12). In a less clear-cut case for Cape Town, despite consistency among global model future projections, there is *medium confidence* in a projected future drier climate due to the lack of consistency in links between increasing greenhouse gases, changes in a key mode of variability (the Southern Annular Mode) and drought in Cape Town among different observation periods and in model simulations. {10.5.3, 10.6, 10.6.2, 10.6.4, Cross-Chapter Box 10.3, 12.4}

Since the AR5, physical climate storyline approaches have emerged as a complementary instrument to provide a different perspective on or additional climate information, to facilitate communication of the information or provide a more flexible consideration of risk. Storylines that condition climatic events and processes on a set of plausible but distinct large-scale climatic changes enable the exploration of uncertainties in regional climate projections. For example, they can explicitly address low-likelihood, high-impact outcomes, which would be

ACCEPTED VERSION SUBJECT TO FINAL EDITING

less emphasized in a probabilistic approach, and can be embedded in a user's risk landscape, taking account of socio-economic factors as well as physical climate changes. Storylines can also be used to communicate climate information by narrative elements describing and contextualising the main climatological features and the relevant consequences in the user context and, as such, can be used as part of a climate information distillation process. {1.4.4., Box 10.2, Box 11.2, 11.2, Cross-chapter Box 12.2}

[START BOX TS.11 HERE]

Box TS.11: Climate Services

Climate services involve providing climate information to assist decision-making, for example, about how extreme rainfall will change to inform improvements in urban drainage. Since AR5, there has been a significant increase in the range and diversity of climate service activities (*very high confidence*). The level of user-engagement, co-design and co-production are factors determining the utility of climate services, while resource limitations for these activities constrain their full potential. {12.6, Cross-Chapter Box 12.2}

Climate services include engagement from users and providers and an effective access mechanism; they are responsive to user needs and based on integrating scientifically credible information and relevant expertise. Climate services are being developed across regions, sectors, time scales and users-groups and include a range of knowledge brokerage and integration activities. These involve identifying knowledge needs; compiling, translating and disseminating knowledge; coordinating networks and building capacity through informed decision-making; analysis, evaluation and development of policy; and personal consultation.

Since AR5, climate change information produced in climate service contexts has increased significantly due to scientific and technological advancements and growing user awareness, requirements, and demand (*very high confidence*). Climate services are growing rapidly and are highly diverse in their practices and products. The decision-making context, level of user engagement and co-production between scientists, practitioners and intended users are important determinants of the type of climate service developed and their utility for supporting adaptation, mitigation and risk management decisions. They require different types of user–producer engagement depending on what the service aims to deliver (*high confidence*), and these fall into three broad categories: website-based services, interactive group activities and focused relationships.

Realization of the full potential of climate services is often hindered by limited resources for the co-design and co-production process, including sustained engagement between scientists, service providers and users (*high confidence*). Further challenges relate to the development and provision of climate services, generation of climate service products, communication with users, and evaluation of their quality and socio-economic benefit. {TS.4.1, 1.2.3, 10.5.4, 12.6, Cross-Chapter Box 12.2, Glossary}

[END BOX TS.11 HERE]

[START BOX TS.12 HERE]

Box TS.12: Multiple Lines of Evidence for Assessing Regional Climate Change and the Interactive Atlas

A key novel element in the AR6 is the WGI Atlas, which includes the Interactive Atlas. The Interactive Atlas provides the ability to explore much of the observational and climate model data used as lines of evidence in this assessment to generate regional climate information. {10.6.4, Atlas.2, Interactive Atlas}

A significant innovation in the AR6 WGI report is the Atlas. Part of its remit is to provide region-by-region assessment on changes in mean climate and to link with other WGI chapters to generate climate change information for the regions. An important component is the new online interactive tool, the Interactive Atlas,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

with flexible spatial and temporal analyses of much of the observed, simulated past and projected future climate change data underpinning the WGI assessment. This includes the ability to generate global maps and a number of regionally aggregated products (time series, scatter plots, tables, etc.) for a range of observations and ensemble climate change projections of variables (such as changes in the CIDs summarized in Table TS.5) from CMIP5, CORDEX and CMIP6. The data can be displayed and summarized under a range of SSP-RCP scenarios and future time slices and also for different global warming levels, relative to several different baseline periods. The maps and various statistics can be generated for annual mean trends and changes or for any user-specified season. A new set of WGI reference regions is used for the regional summary statistics and applied widely throughout the report (with the regions available, along with aggregated datasets and the code to generate these at the ATLAS GitHub: https://github.com/IPCC-WG1/Atlas).

Box TS.12, Figure 1 shows how the Interactive Atlas products, together with other lines of evidence, can be used to generate climate information for an illustrative example of the Mediterranean summer warming. The lines of evidence include the understanding of relevant mechanisms, dynamic and thermodynamic processes and the effect of aerosols in this case (Box TS.12, Figure 1a), trends in observational datasets (which can have different spatial and temporal coverage – Box TS.12, Figure 1b, c), attribution of these trends and temperature projections from global and regional climate models at different resolutions, including single-model initial-condition large ensembles (SMILEs; Box TS.12, Figure 1d, e). Taken together, this evidence shows there is *high confidence* that the projected Mediterranean summer temperature increase will be larger than in the global mean with consistent results from CMIP5 and CMIP6 (Box TS.12, Figure 1e). However, CMIP6 results project both more pronounced warming than CMIP5 for a given emissions scenario and time period and a greater range of changes (Box TS.12, Figure 1d). {10.6.4, Atlas.2, Interactive Atlas}

[START BOX TS.12, FIGURE 1 HERE]

Box TS.12, Figure 1: **Example of generating regional climate information from multiple lines of evidence for the case of Mediterranean summer warming, with indication of the information available from the Interactive Atlas.** (a) Mechanisms and feedbacks involved in enhanced Mediterranean summer warming. (b) Locations of observing stations from different datasets. (c) Distribution of 1960–2014 summer temperature trends (°C per decade) for observations (black crosses), CMIP5 (blue circles), CMIP6 (red circles), HighResMIP (orange circles), CORDEX EUR-44 (light blue circles), CORDEX EUR-11 (green circles), and selected single Model Initial-condition Large Ensembles - SMILEs (grey boxplots, MIROC6, CSIRO-Mk3-6-0, MPI-ESM and d4PDF). (d) Time series of area averaged (25°N–50°N, 10°W–40°E) land point summer temperature anomalies (°C, baseline period is 1995–2014): the boxplot shows long term (2081–2100) temperature changes of different CMIP6 scenarios in respect to the baseline period. (e) Projected Mediterranean summer warming in comparison to global annual mean warming of CMIP5 (RCP2.6, RCP4.5, RCP6.0 and RCP8.5) and CMIP6 (SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5) ensemble means (lines) and spread (shading). {Figure 10.20, Figure 10.21, Figure Atlas.8}

[END BOX TS.12, FIGURE 1 HERE]

[END BOX TS.12 HERE]

TS.4.2 Drivers of Regional Climate Variability and Change

Anthropogenic forcing, including GHGs and aerosols but also regional land use and irrigation have all affected observed regional climate changes (*high confidence*) and will continue to do so in the future (*high confidence*), with various degrees of influence and response times, depending on warming levels, the nature of the forcing and the relative importance of internal variability. Since the late 19th century, major modes of variability (MoVs) exhibited fluctuations in frequency and magnitude at multi-decadal time scales, but no sustained trends outside the range of internal variability (Table TS.4). An exception is the Southern Annular Mode (SAM), which has become systematically more positive (*high confidence*) and is projected to be more positive in all seasons, except for December-January-February (DJF), in high CO_2 emissions scenarios (*high confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The influence of stratospheric ozone forcing on the SAM trend has been reduced since the early 2000s compared to earlier decades, contributing to the weakening of its positive trend as observed over 2000–2019 (*medium confidence*). In the near-term, projected changes in most of the MoVs and related teleconnections will *likely* be dominated by internal variability. In the long-term, it is *very likely* that the precipitation variance related to El Niño–Southern Oscillation will increase. Physical climate storylines, including the complex interplay between climate drivers, MoVs, and local and remote forcing, increase confidence in the understanding and use of observed and projected regional changes. {2.4, 3.7, 4.3, 4.4, 4.5, 6.4, 8.3, 8.4, 10.3, 10.4, 11.3}

TS.4.2.1 Regional Fingerprints of Anthropogenic and Natural Forcing

While anthropogenic forcing has contributed to multi-decadal mean precipitation changes in several regions, internal variability can delay emergence of the anthropogenic signal in long-term precipitation changes in many land regions (*high confidence*). At the regional scale, the effect of human-induced GHG forcing on extreme temperature is moderated or amplified by soil moisture feedback, snow/ice-albedo feedback, regional forcing from land-use/land-cover changes, forcing from aerosol concentrations, or decadal/multi-decadal natural variability. Changes in local and remote aerosol forcings lead to south-north gradients of the effective radiative forcing (ERF) (hemispherical asymmetry). Along latitudes, it is more uniform with strong amplification of the temperature response towards the Arctic (*medium confidence*). The decrease of SO_2 emissions since the 1980s reduces the damping effect of aerosols, leading to a faster increase in surface air temperature that is most pronounced at mid- and high latitudes of the Northern Hemisphere, where the largest emission reductions have taken place (*medium confidence*). {1.3, 3.4.1, 6.3.4, 6.4.1, 6.4.3, 8.3.1, 8.3.2, Box 8.1, 10.4.2, 10.6, 11.1.6, 11.3}

Multidecadal dimming and brightening trends in incoming solar radiation at the Earth's surface occurred at widespread locations (*high confidence*). Multi-decadal variation in anthropogenic aerosol emissions are thought to be a major contributor (*medium confidence*), but multi-decadal variability in cloudiness may also have played a role. Volcanic eruptions affect regional climate through their spatially heterogeneous effect on the radiative budget as well as through triggering dynamical responses by favouring a given phase from some MoVs, for instance. {1.4.1, Cross-Chapter Box 1.2, 2.2.1, 2.2.2, 3.7.1, 3.7.3, 4.3.1, 4.4.1, 4.4.4, Cross-Chapter Box 4.1, 7.2.2, 8.5.2, 10.1.4, 11.1.6, 11.3.1}

Historical urbanization affects the observed warming trends in cities and their surroundings (*very high confidence*). Future urbanization will amplify the projected air temperature under different background climates, with a strong effect on minimum temperatures that could be as large as the global warming signal (*very high confidence*). Irrigation and crop expansion have attenuated increases in summer hot extremes in some regions, such as central North America (*medium confidence*). {Box 10.3, 11.1.6, 11.3, Box TS.6, Box TS.14}

TS.4.2.2 Modes of Variability and Regional Teleconnections

Modes of Variability (MoVs) (Annex IV, Table TS.4) have existed for millennia or longer (*high confidence*), but there is *low confidence* in detailed reconstructions of most of them prior to direct instrumental records. MoVs are treated as a main source of uncertainties associated with internal dynamics, as they can either accentuate or dampen, even mask, the anthropogenically-forced responses. {2.4, 8.5.2, 10.4, 10.6, 11.1.5, Atlas.3.1}

Since the late 19th century, major MoVs (Table TS.4) show no sustained trends, exhibiting fluctuations in frequency and magnitude at multi-decadal time scales, except for the Southern Annular Mode (SAM), which has become systematically more positive (*high confidence*) (Table TS.4). It is *very likely* that human influence has contributed to this trend from the 1970s to the 1990s, and to the associated strengthening and southward shift of the Southern Hemispheric extratropical jet in austral summer. The influence of stratospheric ozone forcing on the SAM trend has been reduced since the early 2000s compared to earlier decades, contributing to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

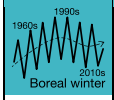
the weakening of its positive trend observed over 2000–2019 (*medium confidence*). By contrast, the cause of the Northern Annular Mode (NAM) trend toward its positive phase since the 1960s and associated northward shifts of Northern Hemispheric extratropical jet and storm track in boreal winter is not well understood. The evaluation of model performance on simulating MoVs is assessed in TS.1.2.2. {2.3.3, 2.4, 3.3.3, 3.7.1, 3.7.2}

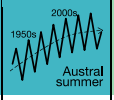
In the near term, the forced change in SAM in austral summer is *likely* to be weaker than observed during the late 20th century under all five SSPs assessed. This is because of the opposing influence in the near- to mid-term from stratospheric ozone recovery and increases in other greenhouse gases on the Southern Hemisphere summertime mid-latitude circulation (*high confidence*). In the near term, forced changes in the SAM in austral summer are therefore *likely* to be smaller than changes due to natural internal variability. In the long-term (2081–2100) under the SSP5-8.5 scenario, the SAM index is *likely* to increase in all seasons relative to 1995–2014. The CMIP6 multi-model ensemble projects a long-term (2081–2100) increase in the boreal wintertime NAM index under SSP3-7.0 and SSP5-8.5, but regional associated changes may deviate from a simple shift in the mid-latitude circulation due to a modified teleconnection resulting from interaction with a modified mean background state. {4.3.3, 4.4.3, 4.5.1, 4.5.3, 8.4.2}

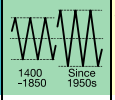
Human influence has not affected the principal tropical modes of interannual climate variability (Table TS.4) and their associated regional teleconnections beyond the range of internal variability (*high confidence*). It is *virtually certain* that the ENSO will remain the dominant mode of interannual variability in a warmer world. There is no consensus from models for a systematic change in amplitude of ENSO SST variability over the 21st century in any of the SSP scenarios assessed (*medium confidence*). However, it is *very likely* that rainfall variability related to ENSO will be enhanced significantly by the latter half of the 21st century in the SSP2-4.5, SSP3-7.0, and SSP5-8.5 scenarios, regardless of the amplitude changes in SST variability related to the mode It is *very likely* that rainfall variability related to changes in the strength and spatial extent of ENSO teleconnections will lead to significant changes at regional scale. {3.7.3, 3.7.4, 3.7.5, 4.3.3, 4.5.3, 8.4.2, 10.3.3}

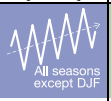
Modes of decadal and multidecadal variability over the Pacific and Atlantic Ocean exhibit no significant changes in variance over the period of observational records (*high confidence*). There is *medium confidence* that anthropogenic and volcanic aerosols contributed to observed temporal evolution in the Atlantic Multidecadal Variability (AMV) and associated regional teleconnections, especially since the 1960s, but there is *low confidence* in the magnitude of this influence and the relative contributions of natural and anthropogenic forcings. Internal variability is the main driver of Pacific Decadal Variability (PDV) observed since the start of the instrumental records (*high confidence*), despite some modelling evidence for potential external influence. There is *medium confidence* that the AMV will undergo a shift towards a negative phase in the near-term. {2.4, 3.7.6, 3.7.7, 8.5.2, 4.4.3}

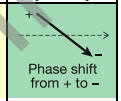
[START TABLE TS.4 HERE]

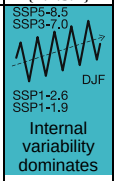


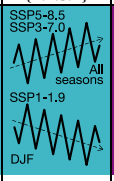


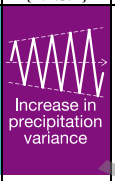


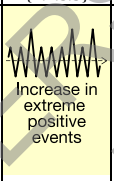












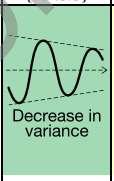


Table TS.4: Summary of the assessments on modes of variability (MoVs) and associated teleconnections. (a) Assessments on observed changes since the start of instrumental records, CMIP5 and CMIP6 model performance, human influence on the observed changes, and near-term (2021–2040) and mid- to long-term (2041–2100) changes. Curves schematically illustrate the assessed overall changes, with the horizontal axis indicating time, and are not intended to precisely represent the time evolution. (b) Fraction of surface air temperature (SAT) and precipitation (pr) variance explained at interannual timescale by each MoV for each AR6 region (numbers in each cell; in percent). Values correspond to the average of significant explained variance fractions based on HadCRUT, GISTEMP, BerkeleyEarth and CRU-TS (for SAT) and GPCC and CRU-TS (for precipitation). Significance is tested based on F-statistics at the 95% level confidence, and a slash indicates that the value is not significant in more than half of the available data sets. The colour scale corresponds to the sign and values of the explained variance as shown at the bottom. The corresponding anomaly maps are shown in Annex IV. DJF: December-January-February. MAM: March-April-May. JJA: June-July-August. SON: September-October-November. In (b), Northern Annular Mode (NAM) and El Niño–Southern Oscillation (ENSO) teleconnections are evaluated for 1959–2019, Southern Annular Mode (SAM) for 1979–2019, Indian Ocean Basin (IOB), Indian Ocean Dipole (IOD), Atlantic Zonal Mode (AZM) and Atlantic Meridional

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Mode (AMM) for 1958–2019, and Pacific Decadal Variability (PDV) and Atlantic Multidecadal Variability (AMV) for 1900–2019. All data are linearly detrended prior to computation. {2.4, 3.7, 4.3.3, 4.4.3, 4.5.3, Table Atlas.1, Annex IV, TS.1.2.2}

TS.4.2.3 Interplay Between Drivers of Climate Variability and Change at Regional Scales

Anthropogenic forcing has been a major driver of regional mean temperature change since 1950 in many subcontinental regions of the world (*virtually certain*). At regional scales, internal variability is stronger, and uncertainties in observations, models and external forcing are all larger than at the global scale, hindering a robust assessment of the relative contributions of greenhouse gases, stratospheric ozone, and different aerosol species in most of the cases. Multiple lines of evidence, combining multi-model ensemble global projections with those coming from single-model initial-condition large ensembles, show that internal variability is largely contributing to the delayed or absent emergence of the anthropogenic signal in long-term regional mean precipitation changes (*high confidence*). Internal variability in ocean dynamics dominates regional patterns on annual to decadal time scales (*high confidence*). The anthropogenic signal in regional sea level change will emerge in most regions by 2100 (*medium confidence*). {9.2.4, 9.6.1, 10.4.1, 10.4.2, 10.4.3}

Regional climate change is subject to the complex interplay between multiple external forcings and internal variability. Time evolution of mechanisms operating at different time scales can modify the amplitude of the regional-scale response of temperature, and both the amplitude and sign of the response of precipitation, to anthropogenic forcing (*high confidence*). These mechanisms include non-linear temperature, precipitation and soil moisture feedbacks, slow and fast responses of SST patterns and atmospheric circulation changes to increasing GHGs. Land use and aerosol forcings and land–atmosphere feedback play important roles in modulating regional changes, for instance in weather and climate extremes (*high confidence*). These can also lead to a higher warming of extreme temperatures compared to mean temperature (*high confidence*), and possibly cooling in some regions (*medium confidence*). The soil moisture–temperature feedback was shown to be relevant for past and present-day heat waves based on observations and model simulations. {10.4.3, 11.1.6, 11.3.1}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Southeastern South America (SES) is one of the AR6 WGI reference regions (outlined with black thick contour in Figure TS.21a) and it is used here as an illustrative example of the interplay between drivers of climate variability and change at regional scale. Austral summer (DJF) precipitation positive trends have been observed over the region during 1950–2014. Drivers of this change include MoVs, such as AMV, ENSO, and PDV, as well as external forcing, like GHG increases and ozone depletion together with aerosols (as illustrated in Figure TS.21a). MoVs and external forcing collectively affect climate phenomena, such as the Hadley cell width and strength, Rossby waves activity emerging from the large-scale tropical SST anomalies, and the Southern Hemisphere polar vortex, which are relevant for the region. In fact, local changes over SES in terms of moisture convergence, ascending motion and storm-track locations depend on these climate phenomena, and they are overall responsible for the observed precipitation trends. Projections suggest continuing positive trends in rainfall over SES in the near-term in response to GHG emissions scenarios. Multi-model mean and ensemble spread are not sufficient to characterise situations where different models simulate substantially different or even opposite changes (*high confidence*). In such cases, physical climate storylines addressing possible outcomes for climate phenomena shown to play a role in the variability of the region of interest can aid the interpretation of projection uncertainties. In addition, single-model initial-condition large ensembles of many realisations of internal variability are required to separate internal variability from forced changes (*high confidence*) and to partition the different sources of uncertainties as a function of future assessed periods. {10.3.4, 10.4.2, Figure 10.12a}

[START FIGURE TS.21 HERE]

Figure TS.21: Example of the interplay between drivers of climate variability and change at regional scale to understand past and projected changes. *The figure intent is to show an illustrative pathway for understanding past, and anticipating future, climate change at regional scale in the presence of uncertainties.* (a) Identification of the climate drivers and their influences on climate phenomena contributing through teleconnection to Southeastern South America summer (DJF) precipitation variability and trends observed over 1950–2014. Drivers (red squares) include MoVs as well as external forcing. Observed precipitation linear trend from GPCC is shown on continents (green-brown colour bar in mm month^{-1} per decade) and the SES AR6 WGI reference region is outlined with the thick black contour. Climate phenomena leading to local effect on SES are schematically presented (blue ovals). (b) Time series of decadal precipitation anomalies for DJF SES simulated from seven large ensembles of historical + RCP8.5 simulations over 1950–2100. Shading corresponds to the 5th–95th range of climate outcomes given from each large ensemble for precipitation (in mm/month) and thick coloured lines stand for their respective ensemble mean. The thick timeseries in white corresponds to the multi-model multi-member ensemble mean with model contribution being weighted according to their ensemble size. GPCC observation is shown in the light black line with squares over 1950–2014 and the 1995–2014 baseline period has been retained for calculation of anomalies in all datasets. (c) Quantification of the respective weight (in percent) between the individual sources of uncertainties (internal in grey, model in magenta and scenario in green) at near-term, mid-term and long-term temporal windows defined in AR6 and highlighted in (b) for SES DJF precipitation. All computations are done with respect to 1995–2014, taken as the reference period and the scenario uncertainty is estimated from CMIP5 using the same set of models as for the large ensembles that have run different RCP scenarios. {Figure 10.12a}

[END FIGURE TS.21 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[START BOX TS.13 HERE]

Box TS.13: Monsoons

Global land monsoon precipitation decreased from the 1950s to the 1980s, partly due to anthropogenic aerosols, but has increased since then in response to GHG forcing and large-scale multi-decadal variability (*medium confidence*). Northern Hemispheric anthropogenic aerosols weakened the regional monsoon circulations in South Asia, East Asia and West Africa during the second half of the 20th century, thereby offsetting the expected strengthening of monsoon precipitation in response to GHG-induced warming (*high confidence*). During the 21st century, global land monsoon precipitation is projected to increase in response to GHG warming in all time horizons and scenarios (*high confidence*). Over South and Southeast Asia, East Asia and the central Sahel, monsoon precipitation is projected to increase, whereas over North America and the far western Sahel it is projected to decrease (*medium confidence*). There is *low confidence* in projected precipitation changes in the South American and Australian-Maritime Continent monsoons. At global and regional scales, near-term monsoons changes will be dominated by the effects of internal variability (*medium confidence*). {2.3, Cross-Chapter Box 2.4, 3.3, 4.4, 4.5, 8.2, 8.3, 8.4, 8.5, Box 8.1, Box 8.2, 10.6}

Global Monsoon

Paleoclimate records indicate that during warm climates, like the mid-Pliocene Warm Period, monsoon systems were stronger (*medium confidence*). In the instrumental records, global summer monsoon precipitation intensity has *likely* increased since the 1980s, dominated by Northern Hemisphere summer trends and large multi-decadal variability. Contrary to the expected increase of precipitation under global warming, the Northern Hemisphere monsoon regions experienced declining precipitation from the 1950s to 1980s, which is partly attributable to the influence of anthropogenic aerosols (*medium confidence*) (Box TS.13, Figure 1). {2.3.1, Cross-Chapter Box 2.4, 3.3.2, 3.3.3}

With continued global warming, it is *likely* that global land monsoon precipitation will increase during this century (Box TS.13, Figure 1), particularly in the Northern Hemisphere, although the monsoon circulation is projected to weaken. A slowdown of the tropical circulation with global warming can partly offset the warming-induced strengthening of precipitation in monsoon regions (*high confidence*). In the near term, global monsoon changes are *likely* to be dominated by the effects of internal variability and model uncertainties (*medium confidence*). In the long term, global monsoon rainfall change will feature a robust north-south asymmetry characterized by a greater increase in the Northern Hemisphere than in the Southern Hemisphere and an east-west asymmetry characterized by enhanced Asian-African monsoons and a weakened North American monsoon (*medium confidence*). {4.4.1, 4.5.1, 8.4.1}

Regional Monsoons

Paleoclimate reconstructions indicate stronger monsoons in the Northern Hemisphere but weaker ones in the Southern Hemisphere during warm periods, particularly for the South and Southeast Asian, East Asian, North and South American monsoons, with the opposite occurring during cold periods (*medium confidence*). It is *very likely* that Northern Hemispheric anthropogenic aerosols weakened the regional monsoon circulations in South Asia, East Asia and West Africa during the second half of the 20th century, thereby offsetting the expected strengthening of monsoon precipitation in response to GHG-induced warming (Box TS.13, Figure 1). Multiple lines of evidence explain this contrast over South Asia, with the observed trends dominated by the effects of aerosols, while future projections are mostly driven by GHG increases. The recent partial recovery and enhanced intensity of monsoon precipitation over West Africa is related to the growing influence of GHGs with an additional contribution due to the reduced cooling effect of anthropogenic aerosols, emitted largely from North America and Europe (*medium confidence*). For other regional monsoons, that is, North and South America and Australia, there is *low confidence* in the attribution of recent changes in precipitation (Box TS.13, Figure 1) and winds. {2.3.1, 8.3.1, 8.3.2, Box 8.1, 10.6.3}

Projections of regional monsoons during the 21st century indicate contrasting (region-dependent) and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

uncertain precipitation and circulation changes. The annual contrast between the wettest and driest month of the year is *likely* to increase by 3–5% per degree Celsius in most monsoon regions in terms of precipitation, precipitation minus evaporation, and runoff (*medium confidence*). For the North American monsoon, projections indicate a decrease in precipitation, whereas increased monsoon rainfall is projected over South and Southeast Asia and over East Asia (*medium confidence*) (Box TS.13, Figure 1). West African monsoon precipitation is projected to increase over the central Sahel and decrease over the far western Sahel (*medium confidence*). There is *low confidence* in projected precipitation changes in the South American and Australian-Maritime Continent regional monsoons (for both magnitude or sign) (Box TS.13, Figure 1). There is *medium confidence* that the monsoon season will be delayed in the Sahel and *high confidence* that it will be delayed in North and South America. {8.2.2, 8.4.2.4, Box 8.2}

Building the Assessment from Multiple Lines of Evidence

Large natural variability of monsoon precipitation across different time scales, found in both paleoclimate reconstructions and instrumental measurements, poses an inherent challenge for robust quantification of future changes in precipitation at regional and smaller spatial scales. At both global and regional scales, there is *medium confidence* that internal variability contributes the largest uncertainty related to projected changes, at least in the near term (2021–2040). A collapse of the Atlantic Multidecadal Overturning Circulation (AMOC) could weaken the African and Asian monsoons but strengthen the Southern Hemisphere monsoons (*high confidence*). {4.4.4, Cross-Chapter Box 4.1, 4.5.1, 8.5.2, 8.6.1, 9.2.3, 10.6.3}

Overall, long-term (2081–2100) future changes in regional monsoons like the South and Southeast Asian monsoon are generally consistent across global (including high-resolution) and regional climate models and supported by theoretical arguments. Uncertainties in simulating the observed characteristics of regional monsoon precipitation are related to varying complexities of regional monsoon processes and their responses to external forcing, internal variability, and deficiencies in representing monsoon warm rain processes, organized tropical convection, heavy orographic rainfall and cloud–aerosol interactions. {8.3.2, 8.5.1, 10.3.3, 10.6.3}

[START BOX TS.13, FIGURE 1 HERE]

Box TS.13, Figure 1: Global and regional monsoons: past trends and projected changes. *The intent of this figure is to show changes in precipitation over regional monsoon domains in terms of observed past trends, how greenhouse gases and aerosols relate to these changes, and in terms of future projections in one intermediate emission scenario in the near, medium and long terms.* (a) Global (black contour) and regional monsoons (colour shaded) domains. The global monsoon (*GM*) is defined as the area with local summer-minus-winter precipitation rate exceeding 2.5 mm day^{-1} (see Annex V). The regional monsoon domains are defined based on published literature and expert judgement (see Annex V), and also accounting for the fact that the climatological summer monsoon rainy season varies across the individual regions. Assessed regional monsoons are South and Southeast Asia (*SAsiaM, Jun-Jul-Aug-Sep*), East Asia (*EAsiaM, Jun-Jul-Aug*), West Africa (*WAfriM, Jun-Jul-Aug-Sep*), North America (*NAmerM, Jul-Aug-Sep*), South America (*SAmerM, Dec-Jan-Feb*), Australia and Maritime Continent Monsoon (*AusMCM, Dec-Jan-Feb*). Equatorial South America (*EqSAmer*) and South Africa (*SAfri*) regions are also shown, as they receive unimodal summer seasonal rainfall although their qualification as monsoons is subject to discussion. (b) Global and regional monsoons precipitation trends based on DAMIP CMIP6 simulations with both natural and anthropogenic (ALL), GHG only (GHG), aerosols only (AER) and natural only (NAT) radiative forcing. Weighted ensemble means are based on nine CMIP6 models contributing to the MIP (with at least 3 members). Observed trends computed from CRU GPCP, and APHRO (only for *SAsiaM* and *EAsiaM*) datasets are shown as well. (c) Percentage change in projected seasonal mean precipitation over global and regional monsoons domain in the near-term (2021–2040), mid-term (2041–2060), and long-term (2081–2100) under SSP2-4.5 based on 24 CMIP6 models. {Figure 8.11, Figure 8.22}

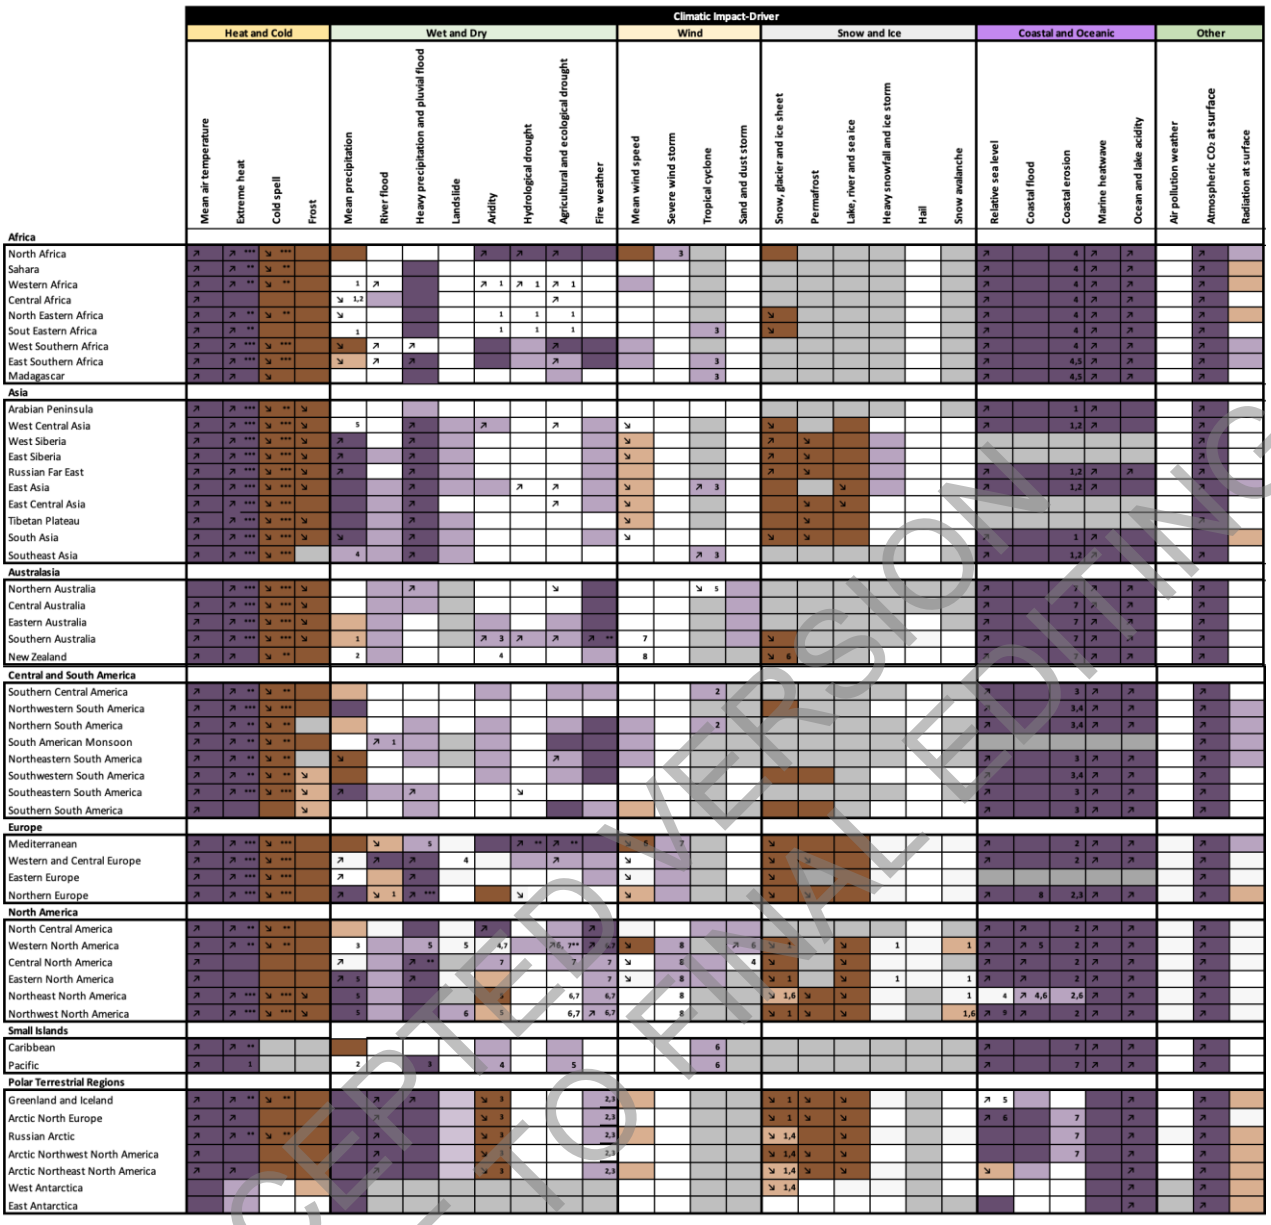
ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END BOX TS.13 HERE]

TS.4.3 Regional Climate Change and Implications for Climate Extremes and Climatic Impact-Drivers



Current climate in all regions is already distinct from the climate of the early or mid-20th century with respect to several climatic impact-drivers (CIDs), resulting in shifting magnitude, frequency, duration, seasonality, and spatial extent of associated climate indices (*high confidence*). It is *very likely* that mean temperatures have increased in all land regions and will continue to increase at rates greater than the global average (*high confidence*). The frequency of heat and cold extremes have increased and decreased, respectively. These changes are attributed to human influence in almost all regions (*medium to high confidence*) and will continue through the 21st century (*high confidence*). In particular, extreme heat would exceed critical thresholds for health, agriculture and other sectors more frequently by the mid 21st century with 2°C of global warming (*high confidence*). Relative sea level rise is *very likely* to *virtually certain* (depending on the region) to continue during the 21st century, contributing to increased coastal flooding in low-lying areas (*high confidence*) and coastal erosion along most sandy coasts (*high confidence*). Sea level will continue to rise beyond 2100 (*high confidence*). Every region of the world will experience concurrent changes in multiple CIDs by mid-century (*high confidence*). Even for the current climate, climate change-induced shifts in CID distributions and event probabilities, some of which have occurred over recent decades, are relevant for risk assessments.{Box TS.4, 11.9, 12.1, 12.2, 12.4, 12.5, Atlas.3–Atlas.11}

An overview of changes in regional CIDs (introduced in TS.1) is given in Table TS.5, which summarizes multiple lines of evidence on regional climate change derived from observed trends, attribution of these trends and future projections. The level of confidence and the amplitude in the projected direction of change in CIDs at a given time-horizon depends on climate change mitigation efforts over the 21st century. It is evident from Table TS.5 that many heat, cold, snow and ice, coastal and oceanic CID changes are projected with *high confidence* in most regions starting from a global warming level (GWL) of 2°C, indicating worldwide challenges. Changes in many other regional CIDs have higher confidence later in the 21st century or at higher GWLs (*high confidence*), and another small subset are projected with *high confidence* for the 1.5°C GWL. This section focuses on the 2°C GWL and mid-century time period because the signal emerges from natural variability for a wider range of CIDs at this higher warming level. Figure TS.22 shows the geographical location of regions belonging to one of five groups characterized by a specific combination of changing climatic impact-drivers (CIDs). {Cross-Chapter Box 10.3, Box 11.1, 10.5, 11.1, 11.9, 12.1, 12.2, 12.4, 12.5}

[START TABLE TS.5 HERE]

Table TS.5: Summary of confidence for climatic impact-driver changes in each AR6 WG I reference region (illustrated in Figure TS.25) across multiple lines of evidence: observed, attributed and projected directional changes. The colours represent their projected aggregate characteristic changes for the mid-21st century, considering scenarios RCP4.5, SSP2-4.5, SRES A1B, or above (RCP6.0, RCP8.5, SSP3-7.0, SSP5-8.5, SRES A2), which approximately encompasses global warming levels of 2.0°C to 2.4°C. Arrows indicate *medium to high confidence* trends derived from observations, and asterisks indicate *medium* and *high confidence* in attribution of observed changes. (North Africa is not an AR6 WGI reference region, but assessment here is based upon the African portion of the Mediterranean reference region). {Tables 12.3–12.11 and Tables 11.4–11.21}

[END TABLE TS.5 HERE]

[START FIGURE TS.22 HERE]

Figure TS.22: (Panel a): shows the geographical location of regions belonging to one of five groups characterized by a specific combination of changing climatic impact-drivers (CIDs). The five groups are represented by the five different colours, and the CID combinations associated with each group are represented in the corresponding 'fingerprint' and text below the map. Each fingerprint comprises a set of CIDs projected to change with *high confidence* in every region in the group, and a second set of CIDs, one or more of which are projected to change in each region with *high* or *medium confidence*. The CID combinations follow a progression from those becoming hotter and drier (group 1) to those becoming hotter and wetter (group 5). In between (groups 2–-4), the CIDs that change include some becoming drier and some wetter and always include a set of CIDs which are getting hotter. Tropical cyclones and severe wind CID changes are represented on the map with black dots in the regions affected. Regions affected by coastal CID changes are described by text on the map. The five groups are chosen to provide a reasonable level of detail for each region-specific detail whilst not overwhelming the map with a full summary all aspects of the assessment, which is available in Table TS.5. [Placeholder: This summary is also represented visually in the Interactive Atlas.] The CID changes summarized in the figure represent *high* and *medium confidence* changes projected if a level of 2°C of global warming is attained around 2050. The bar chart in panel b) shows the numbers of regions where each CID is increasing or decreasing with *medium* or *high confidence* for all land regions reported in the map of panel a) and for the ocean regions. The regions coloured in the map comprise the WG I AR6 reference regions, which include inhabited land areas and an additional non-continuous Pacific Islands region labelled PAC. Definitions of the acronyms of the other regions are provided in Atlas.1 and the Interactive Atlas. {Table TS.5, Figure TS.24}

[END FIGURE TS.22 HERE]

TS.4.3.1 Common Regional Changes in Climatic Impact-Drivers

Heat and cold: Changes in temperature-related CIDs such as mean temperatures, growing season length, and extreme heat and frost have already occurred (*high confidence*), and many of these changes have been attributed to human activities (*medium confidence*). Over all land regions with sufficient data (i.e., all except Antarctica), observed changes in temperature have already clearly emerged outside the range of internal variability, relative to 1850–1900 (Figure TS.24). In tropical regions, recent past temperature distributions have already shifted to a range different to that of the early 20th century (*high confidence*) (TS.1.2.4). Most land areas have *very likely* warmed by at least 0.1°C per decade since 1960, and faster in recent decades. On regional-to-continental scales, trends of increased frequency of hot extremes and decrease of cold extremes are generally consistent with the global-scale trends in mean temperature (*high confidence*). In a few regions, trends are difficult to assess due to limited data availability. {2.3.1.1, 11.3, 11.9, 12.4, Atlas.3.1, Interactive Atlas}

[START FIGURE TS.23 HERE]

Figure TS.23: **Time period during which the signals of temperature change in observed data aggregated over the reference regions emerged from the noise of annual variability in the respective aggregated data, using a signal-to-noise ratio of 2 as the threshold for emergence.** Emergence time is calculated for two global observational datasets, (a) Berkeley Earth and (b) CRUTEM5. Regions in the CRUTEM5 map are shaded grey when data are available over less than 50% of the area of the region. {Figure Atlas.11, TS.1.2.4}

[END FIGURE TS.23 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Warming trends observed in recent decades are projected to continue over the 21st century and over most land regions at a rate higher than the global average (*high confidence*). For given global warming levels, model projections from CMIP6 show future regional warming changes that are similar to those projected by CMIP5. However, projected regional warming in CMIP6 for given time periods and emissions scenarios has a wider range with a higher upper limit compared to CMIP5 because of the higher climate sensitivity in some CMIP6 models and differences in the forcings. {Atlas}

Under RCP8.5/SSP5-8.5, it is *likely* that most land areas will experience further warming of at least 4°C compared to a 1995–2014 baseline by the end of the 21st century, and in some areas significantly more. At increasing warming levels, extreme heat will exceed critical thresholds for health, agriculture and other sectors more frequently (*high confidence*), and it is *likely* that cold spells will become less frequent towards the end of the century. For example, by the end of the 21st century, dangerous humid heat thresholds, such as the NOAA Heat Index (HI) of 41°C, will be exceeded much more frequently under the SSP5-8.5 scenario than under SSP1-2.6 and will affect many regions (*high confidence*). In many tropical regions, the number of days per year where a HI of 41°C is exceeded would increase by more than 100 days relative to the recent past under SSP5-8.5, while this increase will be limited to less than 50 days under SSP1-2.6 (*high confidence*) (Figure TS.6). The number of days per year where temperature exceeds 35°C would increase by more than 150 days in many tropical areas by end of century for SSP5-8.5 scenario, such as the Amazon basin and South East Asia under SSP5-8.5, while it is expected to increase by less than 60 days in these areas under SSP1-2.6 (except for the Amazon Basin) (*high confidence*) (Figure TS.24). {4.6.1, 11.3, 11.9, 12.4, 12.5.2, Atlas}

[START FIGURE TS.24 HERE]

Figure TS.24: Projected change in the mean number of days per year with maximum temperature exceeding 35°C for CMIP5 (first column), CMIP6 (second column) and CORDEX (thirth column). The map shows the median change in the number of days per year between the mid-century (2041–2060) or end-century (2081–2100) and historical (1995–2014) periods for the CMIP5 and CORDEX RCP8.5 and RCP2.6 and CMIP6 SSP5-8.5 and SSP1-2.6 scenarios ensembles. Stippling indicates areas where less than 80% of the models agree on the sign of change. {Interactive Atlas}

[END FIGURE TS.24 HERE]

Wet and dry: Compared to the global scale, precipitation internal variability is stronger at the regional scale while uncertainties in observations, models and external forcing are all larger. However, GHG forcing has driven increased contrasts in precipitation amounts between wet and dry seasons and weather regimes over tropical land areas (*medium confidence*), with a detectable precipitation increase in the northern high latitudes (*high confidence*) (Box TS.6). The frequency and intensity of heavy precipitation events have increased over a majority of land regions with good observational coverage (*high confidence*). A majority of land areas have experienced decreases in available water in dry seasons due to human-induced climate change associated with changes in evapotranspiration (*medium confidence*). Global hydrological models project a larger fraction of land areas to be affected by an increase rather than by a decrease in river floods (*medium confidence*). Extreme precipitation and pluvial flooding will increase in many regions around the world on almost all continents (*high confidence*), but regional changes in river floods are more uncertain than changes in pluvial floods because complex hydrological processes, including land cover and human water management are involved. {Box 8.2, 8.2.2.1, 8.3.1, 10.4.1, 11.5, 11.6, 11.9, 12.4, 12.5.1, Atlas.3.1, Interactive Atlas}

Wind: Observed mean wind speed is decreasing over most land areas where observational coverage is high (*medium confidence*). It is *likely* that the global proportion of major tropical cyclone (TC) intensities (Categories 3–5) over the past four decades has increased. The proportion of intense TCs, average peak TC wind speeds, and peak wind speeds of the most intense TCs will increase on the global scale with increasing global warming (*high confidence*). {11.7.1}

Snow and ice: Many aspects of the cryosphere either have seen significant changes in the recent past or will see them during the 21st century (*high confidence*). Glaciers will continue to shrink and permafrost to thaw in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

all regions where they are present (*high confidence*). Also, it is *virtually certain* that snow cover will experience a decline over most land regions during the 21st century, in terms of water equivalent, extent and annual duration. There is *high confidence* that the global warming-induced earlier onset of spring snowmelt and increased melting of glaciers have already contributed to seasonal changes in streamflow in high-latitude and low-elevation mountain catchments. Nevertheless, it is *very likely* that some high-latitude regions will experience an increase in winter snow water equivalent due to the effect of increased snowfall prevailing over warming-induced increased snowmelt. {TS.2.5, Box 8.2, 8.2.2.1, 8.3.1, 9.4, 9.5.1, 9.5.2, 12.4, Atlas}

Coastal and oceanic: There is *high confidence* that SST will increase in all oceanic regions, excepting the North Atlantic. Regional sea-level change has been the main driver of changes in extreme sea levels across the quasi-global tide gauge network over the 20th century (*high confidence*). With the exception of a few regions with substantial land uplift, relative sea-level rise is *very likely to virtually certain* (depending on the region) to continue along the 21st century, contributing to increased coastal flooding in low-lying areas (*high confidence*) and coastal erosion along most sandy coasts (*high confidence*) over the 21st century. In the open ocean, acidification, changes in sea ice and deoxygenation have already emerged in many areas (*high confidence*). Marine heatwaves (MWHs) are also expected to increase around the globe over the 21st century (*high confidence*). {TS.2.4, Box 9.2, 9.2.1.1, 9.6, 9.6.4, 9.6.4.2, 12.4}

Other variables and concurrent CID changes: It is *virtually certain* that atmospheric CO_2 and oceanic pH will increase in all climate scenarios, until net zero CO_2 emissions are achieved (TS.2.2). In nearly all regions, there is *low confidence* in changes in hail, ice storms, severe storms, dust storms, heavy snowfall, and avalanches, although this does not indicate that these CIDs will not be affected by climate change. For such CIDs, observations are often short-term or lack homogeneity, and models often do not have sufficient resolution or accurate parametrizations to adequately simulate them over climate change time scales. The probability of compound events has increased in the past due to human-induced climate change and will *likely* continue to increase with further global warming, including for concurrent heat waves and droughts, compound flooding and the possibility of connected sectors experiencing multiple regional extreme events at the same time (for example, in multiple breadbaskets) (*high confidence*). {5.3.4.2, 11.8, Box 11.3, Box 11.4, 12.4}

TS.4.3.2 Region-by-Region Changes in Climatic Impact-Drivers

This section provides a continental synthesis of changes in CIDs, some examples of which are presented in Figure TS.25.

With 2°C global warming, and as early as the mid-21st century, a wide range of CIDs, particularly related to the water cycle and storms, are expected to show simultaneous region-specific changes relative to recent past with *high* or *medium confidence*. In a number of regions (Southern Africa, the Mediterranean, North Central America, Western North America, the Amazon regions, South Western South America, and Australia), increases in one or more of drought, aridity and fire weather (*high confidence*) will affect a wide range of sectors, including agriculture, forestry, health and ecosystems. In another group of regions (Northwestern, Central and Eastern North America, Arctic regions, Northwestern South America, Northern and Central Western Europe, Siberia, Central, South and East Asia, Southern Australia and New Zealand), decreases in snow and ice or increases in pluvial/river flooding (*high confidence*) will affect sectors such as winter tourism, energy production, river transportation, and infrastructure. {11.9, 12.3, 12.4, 12.5, Table 12.2}

[START FIGURE TS.25 HERE]

Figure TS.25: Distribution of projected changes in selected climatic impact-driver indices for selected regions for CMIP6, CMIP5 and CORDEX model ensembles. Different indices are shown for different region: for east Europe and north Asia the mean number of days per year with maximum temperature exceeding 35°C, for Central America and the Caribbean, and the Arabian peninsula, western, southern and easten Asia the mean number of days per year with the NOAA Heat Index exceeding 41°C, for Australasia, East Asia and Russia far East the average shoreline position change, for South America,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Europe and Africa the mean change in 1-in-100-years river discharge per unit catchment area (m3 s–1 km–2), and for North America the median change in the number of days with snow water equivalent (SWE) over 100 mm. For each box plot the changes or the climatological values are reported respect to, or compared to, the recent past (1995–2014) period for 1.5 ºC, 2ºC and 4ºC global warming levels and for mid-century (2041–2060) or end-century (2081–2100) periods for the CMIP5 and CORDEX RCP8.5 and RCP2.6 and CMIP6 SSP5-8.5 and SSP1-2.6 scenarios ensembles {Figure 12.5, Figure 12.6, Figure 12.9, Figure 12.SM.1, Figure 12.SM.2, Figure 12.SM.6}.

[END FIGURE TS.25 HERE]

TS.4.3.2.1 Africa

Additional regional changes in Africa, besides those described in TS.4.3.1, include a projected decrease in total precipitation in the northernmost and southernmost regions (*high confidence*), with West and East Africa each having a west-to-east pattern of decreasing-to-increasing precipitation (*medium confidence*). Increases in heavy precipitation that can lead to pluvial floods (*high confidence*) are projected for most African regions, even as increasing dry CIDs (aridity, hydrological, agricultural and ecological droughts, fire weather) are projected in the western part of West Africa, North Africa, South Africa and the Mediterranean regions (*medium to high confidence*). {8.4, 11.3, 11.6, 11.9, 12.4, Atlas.4}

In addition to the main changes summarized above and in TS.4.3.1, additional details per CID are given below.

Heat and cold: Observed and projected increases in mean temperature and a shift toward heat extreme characteristics are broadly similar to the generic pattern described in TS.4.3.1. {2.3.1.1.2, 11.3, 11.9, 12.4.1.1, Atlas.4.2, Atlas.4.4}

Wet and dry: Mean precipitation changes have been observed over Africa, but the historical trends are not spatially coherent (*high confidence*). Northern East Africa, Eastern Southern Africa and Central Africa have experienced a decline in rainfall since about 1980 and parts of West Africa an increase (*high confidence*). Increases in the frequency and/or the intensity of heavy rainfall have been observed in Eastern and Western Southern Africa, and the eastern Mediterranean region (*medium confidence*). Increasing trends in river flood occurrences can be identified beyond 1980 in Eastern and Western Southern Africa (*medium confidence*) and West Africa (*high confidence*). However, Northern Africa and Western Southern Africa are *likely* to have a reduction in precipitation. Over West Africa, rainfall is projected to decrease in the Western Sahel subregion and increase along the Guinea Coast subregion (*medium confidence*). Rainfall is *likely* to reduce over the western part of East Africa but increase in the eastern part of the region (*medium confidence*). {8.3.1.6, 11.4, 11.9, 12.4.1.2, Atlas.4.2, Atlas.4.5, Interactive Atlas}

Precipitation declines and aridity trends in West Africa, Central Africa, Southern Africa and the Mediterranean co-occur with trends towards increased agricultural and ecological droughts in the same regions (*medium confidence*). Trends towards increased hydrological droughts have been observed in the Mediterranean (*high confidence*) and West Africa (*medium confidence*). These trends correspond with projected regional increases in aridity and fire weather conditions (*high confidence*). {8.3.1.6, 8.4.1.6, 11.6, 11.9, 12.4.1.2}

Wind: Mean wind, extreme winds and the wind energy potential in North Africa and the Mediterranean are projected to decrease across all scenarios (*high confidence*). Over West Africa and South Africa, a future significant increase in wind speed and wind energy potential is projected (*medium confidence*). There is a projected decrease in the frequency of tropical cyclones making landfall over Madagascar, Eastern Southern Africa and East Africa (*medium confidence*). {12.4.1.3}

Snow and ice: There is *high confidence* that African glaciers and snow have very significantly decreased in the last decades and that this trend will continue in the 21st century. {12.4.1.4}

Coastal and oceanic: Relative sea level has increased at a higher rate than GMSL around Africa over the last 3 decades. The present day 1-in-100-years Extreme Total Water Level (ETWL) is between 0.1 m and 1.2 m

ACCEPTED VERSION SUBJECT TO FINAL EDITING

around Africa, with values around 1 m or above along the South West, South East and Central East coasts. Satellite-derived shoreline retreat rates up to 1 m yr^{-1} have been observed around the continent from 1984 to 2015, except in Southeastern Africa, which has experienced a shoreline progradation (growth) rate of 0.1 m yr^{-1} over the same period. {12.4.1.5}

TS.4.3.2.2 Asia

Due to the high climatological and geographical heterogeneity of Asia, the assessment findings below are summarised over five sub-continental areas comprising one or more of the AR6 WG I reference regions (Box TS.12): East Asia (EAS+ECA), North Asia (WSB+ESB+RFE), South Asia (SAS+TIB), Southeast Asia (SEA) and Southwest Asia (ARP+WCA).

Additional regional changes in Asia, besides those features described in TS.4.3.1, include historical trends of annual precipitation that show considerable regional differences (*high confidence*). East Asian Monsoon precipitation has changed, with drying in the north and wetting in the south since the 1950s, and annual mean precipitation totals *very likely* have increased over most territories of North Asia since the mid-1970s (*high confidence*). South Asian summer monsoon precipitation decreased over several areas since the mid-20th century (*high confidence*) but is *likely* to increase during the 21st century, with enhanced interannual variability.

Increases in precipitation and rivers floods are projected over much of Asia: in the annual mean precipitation in East, North, South and Southeast Asia (*high confidence*); for extremes in East, South, West Central, North and Southeast Asia (*high confidence*) and Arabian Peninsula (*medium confidence*); and for river floods in East, South and Southeast Asia and East Siberia (*medium confidence*). Aridity in East and West Central Asia is projected to increase, especially beyond the middle of the 21st century and global warming levels beyond 2°C, (*medium confidence*). Fire weather seasons are projected to lengthen and intensify everywhere except Southeast Asia, Tibetan Plateau and Arabian Peninsula (*medium confidence*).

There is a large uncertainty in the future continuation of observed decreasing trends in surface wind speeds in Asia (*high confidence*), with *medium confidence* that mean wind speeds will decrease in North Asia, East Asia and Tibetan Plateau and that tropical cyclones will have decreasing frequency and increasing intensity overall in Southeast and East Asia.

Over North Asia, increases in permafrost temperature and its thawing have been observed over recent decades (*high confidence*). Future projections indicate continuing decline in seasonal snow duration, glacial mass, and permafrost area by mid-century (*high confidence*). Snow-covered areas and snow volumes will decrease in most regions of the Hindu Kush Himalaya during the 21st century and snowline elevations will rise (*high confidence)* and glacier volumes are *likely* to decline with greater mass loss in higher CO_2 emissions scenarios. Heavy snowfall is increasing in East Asia and North Asia (*medium confidence*) but with limited evidence on future changes in hail and snow avalanches.

{2.3, 8.3, 8.4, 9.5, 9.6, 10.6, Box 10.4, 11.4, 11.5, 11.7, 11.9, 12.4.2, Atlas.3.1, Atlas.5, Atlas.5.2, Atlas.5.3, Atlas.5.4, Atlas.5.5, Box TS.13}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Heat and cold: Over all regions of Asia, observed and projected increases in mean temperature and a shift toward heat extreme characteristics are broadly similar to the generic pattern described in TS.4.3.1. Over Southeast Asia annual mean surface temperature will *likely* increase by a slightly smaller amount than the global average. {Atlas.5.4.4}

Wet and dry: Over East Asia, historical trends of annual precipitation show considerable regional differences but with increases over northwest China and South Korea (*high confidence*). Daily precipitation extremes have increased over part of the region (*high confidence*). Extreme hydrological drought frequency has increased in a region extending from southwest to northeast China, with projected increases of agricultural and ecological drought for 4°C GWL and fire weather for 2°C and above (*medium confidence*). {8.3.2, 8.4.2, 11.4.4, 11.4.5,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

11.9, 12.4.2.2, Atlas.5.1.2}

Over North Asia, annual mean precipitation totals have *very likely* increased, causing more intense flooding events, and there is *medium confidence* that the number of dry days has decreased. Concurrently total soil moisture is projected to decline extensively (*medium confidence*). {8.3.1.3, 8.4.1.6, 11.4.5, 11.5.2, 11.5.5, 12.4.2.2, Atlas.5.2.2}

Over South Asia, the summer monsoon precipitation decreased over several areas since the mid-20th century (*high confidence*), while it increased in parts of the western HKH and decreased over eastern-central HKH (*medium confidence*) (Box TS.12). The frequency of heavy precipitation and flood events has increased over several areas during the last few decades (*medium confidence*). {8.3.1.3, 8.3.2.4.1, 8.4.1.5, 8.4.2.4.1, 10.6.3.3, 10.6.3.5, 10.6.3.6, 10.6.3.8, Cross-Chapter Box 10.4, 11.4.1, 11.4.2, 11.4.5, 11.5.5, 12.4.2.2, Box 10.4, Atlas 5.3.2}

Over Southeast Asia, mean precipitation trends are not spatially coherent or consistent across datasets and seasons (*high confidence*). Most of the region has experienced an increase in rainfall intensity but with a reduced number of wet days (*medium confidence*). Rainfall is projected to increase in the northern parts of Southeast Asia and decrease in areas in the Maritime Continent (*medium confidence*). {8.4.1, 11.4.2, 11.5.5, 11.9, 12.4.2.2, Atlas.3.1, Atlas.5.4.2, Atlas.5.4.4}

Over Southwest Asia, an observed annual precipitation decline over the Arabian Peninsula since the 1980s of 6.3 mm per decade is contrasted with observed increases between 1.3 mm and 4.8 mm per decade during 1960–2013 over the elevated part of eastern West Central Asia *(very high confidence)*, along with an increase of the frequency and intensity of extreme precipitation. {Figure 8.19, Figure 8.20, 8.3.1.6, 8.4.1.6, Table 11.2A, 11.9, 12.4.2.2, Atlas.5.5}

Wind: Over East Asia, the terrestrial near-surface wind speed has decreased and is projected to decrease further in the future (*medium confidence*). Since the mid 1980's, there has been an increase in the number and intensification rate of intense TCs (*medium confidence*), with a significant northwestward shift in tracks and a northward shift in their average latitude, increasing exposure over East China, the Korean Peninsula and the Japanese Archipelago (*medium confidence*). {11.7.1, 12.4.2.3}

Over North Asia there is *medium confidence* for a decreasing trend in wind speed during 1979–2018 and for projected continuing decreases of terrestrial near-surface wind speed (*medium confidence*). {2.3.1.4.4, 12.4.2.3}

Over Southeast Asia, although there is no significant long-term trend in the number of TC, fewer but more extreme TCs have affected the Philippines during 1951–2013. {11.7.4, 12.4.2.4}

Snow and ice: Over East Asia, decreases have been observed in the frequency and increases in the mean intensity of snowfall in north-western, north-eastern and south-eastern China and the eastern Tibetan Plateau since the 1960s. Heavy snowfall is projected to occur more frequently in some parts of Japan (*medium confidence*). {12.4.2.4, Atlas.5.1.2}

Over North Asia, seasonal snow duration and extent have decreased in recent decades (*high confidence*), and maximum snow depth *likely* has increased since the mid-1970s, particularly over south of the Russian-Far-East. {2.3.2.5, 8.3.1.7.2, 9.5, 12.4.2.4, Atlas.5.2, Atlas.5.4}

Over South Asia, snow-cover has reduced over most of the HKH since the early 21st century, and glaciers have thinned, retreated, and lost mass since the 1970s (*high confidence*) although the Karakoram glaciers have either slightly gained mass or are in an approximately balanced state (*medium confidence*). {8.3.1.7.1, Cross-Chapter Box 10.4}

Over Southwest Asia, mountain permafrost degradation at high altitudes has increased the instability of mountain slopes in the past decade (*medium confidence*). More than 60% of glacier mass in the Caucasus is

ACCEPTED VERSION
SUBJECT TO FINAL EDITING

projected to disappear under RCP8.5 emissions by the end of the 21st century (*medium confidence*). {9.5.1, 9.5.3, 12.4.2.4}

Coastal and oceanic: Over the last three decades, relative sea level has increased at a rate higher than GMSL around Asia (*high confidence*). Gross coastal area loss and shoreline retreat has been observed over 1984–2015, but with localized shoreline progradation in the Russian Far East, East and Southeast Asia. {12.4.2.5}

Projections show that regional-mean sea level continues to rise (*high confidence*), ranging from 0.4–0.5 m under SSP1-2.6 to 0.8–1.0 m under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values). This will contribute to more frequent coastal flooding and higher Extreme Total Water Level (ETWL) in low-lying areas and coastal erosion along sandy beaches (*high confidence*). There is *high confidence* that compound effects of climate change, land subsidence, and human factors will lead to higher flood levels and prolonged inundation in the Mekong Delta and other Asian coasts. {9.6.1, 9.6.3, 12.4.2.5}

TS.4.3.2.3 Australasia

Additional regional changes in Australasia, besides those features described in TS.4.3.1, include a significant decrease in April to October rainfall in southwest Western Australia, observed from 1910 to 2019 and attributable to human influence (*high confidence*), which is *very likely* to continue in future. Agricultural and ecological and hydrological droughts have increased over southern Australia (*medium confidence*), and meteorological droughts have decreased over northern and central Australia (*medium confidence*). Relative sea level has increased over the period 1993–2018 at a rate higher than GMSL around Australasia (*high confidence*). Sandy shorelines have retreated around the region, except in southern Australia, where a shoreline progradation rate of 0.1 m yr^{-1} has been observed. In the future, heavy precipitation and pluvial flooding are *very likely* to increase over northern Australia and central Australia, and they are *likely* to increase elsewhere in Australasia for global warming levels (GWLs) exceeding 2°C and with *medium confidence* for a 2°C GWL. Agricultural and ecological droughts are projected to increase in southern and eastern Australia (*medium confidence*) for a 2°C GWL. Fire weather is projected to increase throughout Australia (*high confidence*) and New Zealand (*medium confidence*). Snowfall is expected to decrease throughout the region at high altitudes in both Australia (*high confidence*) and New Zealand (*medium confidence*), with glaciers receding in New Zealand (*high confidence*). {11.4, Table 11.6, 12.3, 12.4.3, Atlas.6.4, Atlas.6.5}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Heat and cold: Observed and projected increases in mean temperature and a shift toward heat extreme characteristics are broadly similar to the generic pattern described in TS.4.3.1. {11.9, 12.4.3.1, Atlas.6}

Wet and dry: There is *medium confidence* that heavy precipitation has increased in northern Australia since 1950. Annual mean precipitation is projected to increase in the south and west of New Zealand (*medium confidence*) and is projected to decrease in southwest western Australia (*high confidence*), eastern Australia (*medium confidence*), and in the north and east of New Zealand (*medium confidence*) for a GWL of 2°C. There is *medium confidence* that river flooding will increase in New Zealand and Australia, with higher increases in northern Australia. Aridity is projected to increase with *medium confidence* in southern Australia (*high confidence* in southwest Western Australia), eastern Australia (*medium confidence*) and in the north and east of New Zealand (*medium confidence*) for GWLs around 2°C. {11.4, Table 11.6, 11.9, 12.4.3.2, Atlas.6.2}

Wind: Mean wind speeds are projected to increase in parts of northeastern Australia (*medium confidence*) by the end of the 21st century, under high CO_2 emissions scenarios. TCs in north eastern and north Australia are projected to decrease in number (*high confidence*) but increase in intensity except for 'east coast lows' (*low confidence*). {12.4.3.3}

Snow and ice: Observations in Australia show that the snow season length has decreased by 5% in the last five decades. Furthermore, the date of peak snowfall in Australia has advanced by 11 days over the last 5

ACCEPTED VERSION SUBJECT TO FINAL EDITING

decades. Glacier ice volume in New Zealand has decreased by 33% from 1977 to 2018. {12.4.3.4, Atlas.6.2}

Coastal and oceanic: Observed changes in marine heat waves (MHWs) over the 20th century in the region show an increase in their occurrence frequency, except along the south east coast of New Zealand, an increase in duration per event, and the total number of MHW days per decade, with the change being stronger in the Tasman Sea than elsewhere. The present day 1-in-100-year ETWL is between 0.5–2.5 m around most of Australia, except the northwestern coast where 1-in-100-year ETWL can be as high as 6 m–7 m. {Box 9.1, 12.3.1.5, 12.4.3.5}

TS.4.3.2.4 Central and South America

Additional regional changes in Central and South America, besides those features described in TS.4.3.1, include increases in mean and extreme precipitation in Southeastern South America since the 1960s (*high confidence*) (TS.4.2.3). Decreasing trends in mean precipitation and increasing trends in agricultural and ecological drought are observed over Northeastern South America (*medium confidence*). The intensity and frequency of extreme precipitation and pluvial floods is projected to increase over Southeastern South America, Southern South America, Northern South America, South American Monsoon and Northeastern South America (*medium confidence*) for a 2°C GWL and above. Increases of agricultural and ecological drought are projected in South America Monsoon and Southern South America, and fire weather is projected to increase over several regions (Northern South America, the South American Monsoon, Northeastern South America and Southwestern South America) (*high confidence*). {8.3, 8.4, 11.3, 11.4, 11.9, Table 11.13, Table 11.14, Table 11.15, 12.4.4.2, Atlas.7.1, Atlas.7.2}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Heat and cold: Observed and projected increases in mean temperature and a shift toward heat extreme characteristics are broadly similar to the generic pattern described in TS.4.3.1. {11.3.2, 11.3.5, Table 11.13, 12.4.4.1, Atlas.7.1.2, Atlas.7.2.2, Atlas.7.2.4}

Wet and dry: Mean precipitation is projected to change in a dipole pattern with increases in Northwestern and Southeastern South America and decreases in Northeastern and Southwestern South America (*high confidence*) with further decreases in Northern South America and South Central America (*medium confidence*). In Northern South America and South Central America, aridity and agricultural and ecological droughts are increasing with *medium confidence*. Fire weather is projected to increase over Southern Central America and Southern South America with *medium confidence*. {8.3.1.3, 8.4.2.4.5, 11.4.2, 11.9, Table 11.14, Table 11.15, 12.4.4.2, Atlas.7.2.2, Atlas.7.2.4}

Wind: Climate projections indicate an increase in mean wind speed and in wind power potential over the Amazonian region (Northern South America, South American Monsoon, Northeastern South America) (*medium confidence*). {12.4.4.3}

Snow and ice: Glacier volume loss and permafrost thawing will *likely* continue in the Andes Cordillera under all climate scenarios, causing important reductions in river flow and potentially high-magnitude glacial lake outburst floods. {9.5.1.1, 12.4.4.4}

Coastal and oceanic: Around Central and South America, relative sea level has increased at a higher rate than GMSL in the South Atlantic and the subtropical North Atlantic, and at a rate lower than GMSL in the East Pacific over the last 3 decades. The present day 1-in-100-years ETWL is highest in Southern and Southwestern South America subregions, where it can be as large as 5 to 6 m. Satellite observations for 1984–2015 show shoreline retreat rates along the sandy coasts of Southern Central America, Southeastern South America and Southern South America, while shoreline progradation rates have been observed in Northwestern South America and Northern South America. Over the period 1982–2016, the coastlines experienced at least one MHW per year, and more along the Pacific coast of North Central America and the Atlantic coast of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Southeastern South America. {12.4.4.5}

TS.4.3.2.5 Europe

Additional regional changes in Europe, besides those features described in TS.4.3.1, include observed increases in pluvial flooding in northern Europe and hydrological and agricultural/ecological droughts in the Mediterranean (*high confidence*), which have been attributed to human contribution with *high* and *medium confidence*, respectively. Increased mean precipitation amounts at high latitudes in boreal winter and reduced summer precipitation in southern Europe are projected starting from a 2°C GWL (*high confidence*). Aridity, agricultural and hydrological droughts and fire weather conditions will increase in the Mediterranean region starting from 2°C GWL (*high confidence*). Pluvial flooding will increase everywhere with *high confidence* except for *medium confidence* in the Mediterranean; in Western and Central Europe this also applies to river flooding starting from a 2°C GWL (*high confidence*). Most periglacial processes in Northern Europe are projected to disappear by the end of the 21st century, even for a low warming scenario (*medium confidence*). {8.3, 11.3, 11.9, 12.4.5, 12.5.2, Atlas.8.2, Atlas.8.4}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Heat and cold: Observed and projected increases in mean temperature and a shift toward heat extreme characteristics are broadly similar to the generic pattern described in TS.4.3.1. {11.3, 11.9, 12.4.5.1, 12.5.2, Atlas.8.2, Atlas.8.4}

Wet and dry: There is *medium confidence* that annual mean precipitation in Northern Europe, West and Central Europe and Eastern Europe has increased since the early 20th century and *high confidence* for extreme precipitation. In the European Mediterranean, the magnitude and sign of observed land precipitation trends depend on time period and exact study region (*medium confidence*). There is *medium confidence* that river floods will decrease in Northern, Eastern and Southern Europe for high warming levels. {8.3.1.3, 11.3, 11.9, 12.4.5.2, Atlas.8.2, Atlas.8.4}

Wind: Mean wind speed over land has decreased (*medium confidence*), but the role of human-induced climate change has not been established. There is *high confidence* that mean wind speeds will decrease in Mediterranean areas and *medium confidence* of such decreases in Northern Europe for GWLs exceeding 2°C. The frequency of Medicanes (tropical-like cyclones in the Mediterranean) is projected to decrease (*medium confidence*). {11.9, 12.4.5.3}

Snow and ice: In the Alps, snow cover will decrease below elevations of 1500–2000 m throughout the 21st century (*high confidence*). A reduction of glacier ice volume is projected in the European Alps and Scandinavia with *high confidence* and with *medium confidence* for the timing and mass change rates. {12.4.5.4, 9.5.2}

Coastal and oceanic: Over the last three decades, relative sea level has increased at a lower rate than GMSL in the sub-polar North Atlantic coasts of Europe. The present day 1-in-100-years ETWL is between 0.5–1.5 m in the Mediterranean basin and 2.5–5.0 m in the western Atlantic European coasts, around the United Kingdom and along the North Sea coast, and lower at 1.5–2.5 m along the Baltic Sea coast. Satellite-derived shoreline change estimates over 1984–2015 indicate shoreline retreat rates of around 0.5 m yr^{-1} along the sandy coasts of Central Europe and the Mediterranean and more or less stable shorelines in Northern Europe. Over the period 1982–2016, the coastlines of Europe experienced on average more than 2.0 MHW per year, with the eastern Mediterranean and Scandinavia experiencing 2.5–3 MHWs per year. {12.4.5.5}

TS.4.3.2.6 North America

Additional regional changes in North America, besides those features described in TS.4.3.1, include changes in North American wet and dry CIDs, which are largely organized by the northeast (more wet) to southwest

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(more dry) pattern of mean precipitation change, although heavy precipitation increases are widespread (*high confidence*). Increasing evaporative demand will expand agricultural and ecological drought and fire weather (particularly in summertime) in Central North America, Western North America and North Central America (from *medium* to *high confidence*). Severe wind storms, tropical cyclones, and dust storms in North America are shifting toward more extreme characteristics (*medium confidence*), and both observations and projections point to strong changes in the seasonal and geographic range of snow and ice conditions in the coming decades (*very high confidence*). General findings for relative sea level, coastal flooding and erosion will not apply for areas with substantial land uplift around the Hudson Bay and Southern Alaska. {8.4, 11.4, 11.5, 11.7, 11.9, 12.4, Atlas.9.4}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Heat and cold: Observed and projected increases in mean temperature and a shift toward heat extreme characteristics are broadly similar to the generic pattern described in TS.4.3.1. {11.3, 11.9, 12.4.6.1, Atlas.9.2, Atlas.9.4}

Wet and dry: Annual precipitation increased over parts of Eastern and Central North America during 1960–2015 (*high confidence*) and has decreased in parts of southwestern United States and northwestern Mexico (*medium confidence*). River floods are projected to increase for all North American regions other than north Central America (med*ium confidence*). {8.4.2.4, 11.4, 11.5, 11.9, 12.4.6.2, Atlas.9.2, Atlas.9.4}

Agricultural and ecological drought increases have been observed in Western North America (*medium confidence*), and aridity is projected to increase in the southwestern United States and Northern Central America, with lower summer soil moisture across much of the continental interior (*medium confidence*). {8.4.1, 11.6.2, 12.4.6.2}

Wind: Projections indicate a greater number of the most intense TCs, with slower translation speeds and higher rainfall potential for Mexico's Pacific Coast, the Gulf Coast and the United States East Coast (*medium confidence*). Mean wind speed and wind power potential are projected to decrease in Western North America (*high confidence*), with differences between global and regional models lending *low confidence* elsewhere. {11.4, 11.7, 12.4.6.3}

Snow and ice: It is *very likely* that some high-latitude regions will experience an increase in winter snow water equivalent, due to the snowfall increase prevailing over the warming trend. At sustained GWLs between 3°C and 5°C, nearly all glacial mass in Western Canada and Western North America will disappear (*medium confidence*). {9.5.1, 9.5.3, 12.4.6.4, Atlas.9.4}

Coastal and oceanic: Around North America, relative sea level has increased over the last 3 decades at a rate lower than GMSL in the subpolar North Atlantic and in the East Pacific, while it has increased at a rate higher than GMSL in the subtropical North Atlantic. Observations indicate that episodic coastal flooding is increasing along many coastlines in North America. Shoreline retreat rates of around 1 m yr^{-1} have been observed during 1984–2015 along the sandy coasts of Northwestern North America and Northern Central America, while portions of the United States Gulf Coast have seen a retreat rate approaching 2.5 m yr^{-1}. Sandy shorelines along Eastern North America and Western North America have remained more or less stable during 1984–2014, but a shoreline progradation rate of around 0.5 m yr^{-1} has been observed in Northeastern North America. {12.4.6.5}

TS.4.3.2.7 Small Islands

Additional regional changes in Small Islands, besides those features described in TS.4.3.1, include a *likely* decrease in rainfall during boreal summer in the Caribbean and in some parts of the Pacific islands poleward of 20° latitude in both the Northern and Southern Hemispheres. These drying trends will *likely* continue in coming decades. Fewer but more intense tropical cyclones are projected starting from a 2°C GWL (*medium*

ACCEPTED VERSION SUBJECT TO FINAL EDITING

confidence). {9.6, 11.3, 11.4, 11.7, 11.9, 12.4.7, Atlas.10.2, Atlas.10.4, Cross-Chapter Box Atlas.2}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Heat and cold: It is *very likely* that most Small Islands have warmed over the period of instrumental records, and continued temperature increases in the 21st century will further increase heat stress in these regions. {11.3.2, 11.9, 12.4.7.1, Atlas.10.2, Atlas.10.4, Cross-Chapter Box Atlas.2}

Wet and dry: Observed and projected rainfall trends vary spatially across the Small Islands. Higher evapotranspiration under a warming climate can partially offset future increases or amplify future reductions in rainfall resulting in increased aridity as well as more severe agricultural and ecological drought in the Small Islands (*medium confidence*). {11.4.2, 11.9, 12.4.7.2, Atlas.10.2, Atlas.10.4, Cross-Chapter Box Atlas.1}

Wind: Global changes indicate that Small Islands will face fewer but more intense TCs, with spatial inconsistency in projections given poleward shifts in TC tracks (*medium confidence*). {11.7.1.2, 11.7.1.5, 12.4.7.3}

Coastal and oceanic: Continued relative sea level rise is *very likely* in the ocean around Small Islands and, along with storm surges and waves, will exacerbate coastal inundation with the potential to increase saltwater intrusion into aquifers in small islands. Shoreline retreat is projected along sandy coasts of most small islands (*high confidence*). {9.6.3.3, 12.4.7.4, Cross-Chapter Box Atlas.1}

TS.4.3.2.8 Polar

It is *virtually certain* that surface warming in the Arctic will continue to be more pronounced than the global average warming over the 21st century. An intensification of the polar water cycle will increase mean precipitation, with precipitation intensity becoming stronger and more *likely* to be rainfall rather than snowfall (*high confidence*). Permafrost warming, loss of seasonal snow cover, and glacier melt will be widespread (*high confidence*). There is *high confidence* that both the Greenland and Antarctic Ice Sheets have lost mass since 1992 and will continue to lose mass throughout this century under all emissions scenarios. Relative sea level and coastal flooding are projected to increase in areas other than regions with substantial land uplift (*medium confidence*). {2.3, 3.4, 4.3, 4.5, 7.4, 8.2, 8.4, Box 8.2, 9.5, 12.4.9, Atlas.11.1, Atlas.11.2}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Heat and cold: Changes in Antarctica showed larger spatial variability, with *very likely* warming in the Antarctic Peninsula since the 1950s and no overall trend in East Antarctica. Less warming and weaker polar amplification are projected as *very likely* over the Antarctic than in the Arctic, with a weak polar amplification projected as *very likely* by the end of the 21st century. {4.3.1, 4.5.1, 7.4.4, 12.4.9.1, Atlas.11.1, Atlas.11.2}

Wet and dry: Recent decades have seen a general decrease in Arctic aridity (*high confidence*), with increased moisture transport leading to higher precipitation, humidity and streamflow and a corresponding decrease in dry days. Antarctic precipitation showed a positive trend during the 20th century. The water cycle is projected to intensify in both polar regions, leading to higher precipitation totals (and a shift to more heavy precipitation) and higher fraction of precipitation falling as rain. In the Arctic, this will result in higher river flood potential and earlier meltwater flooding, altering seasonal characteristics of flooding (*high confidence*). A lengthening of the fire season (*medium confidence*) and encroachment of fire regimes into tundra regions (*high confidence*) are projected. {8.2.3, 8.4.1, Box 8.2, 9.4.1, 9.4.2, 12.4.9.2, Atlas.11.1, Atlas.11.2}

Wind: There is *medium confidence* in mean wind decrease over the Russian Arctic and Arctic Northeast North America, but *low confidence* of changes in other Arctic regions and Antarctica. {12.4.9.3}

Snow and ice: Reductions in spring snow cover extent have occurred across the Northern Hemisphere since at least 1978 (*very high confidence*). Permafrost warming and thawing have been widespread in the Arctic

ACCEPTED VERSION SUBJECT TO FINAL EDITING

since the 1980s (*high confidence*), causing strong heterogeneity in surface conditions. There is *high confidence* in future glacier and ice sheet loss, permafrost warming, decreasing permafrost extent and decreasing seasonal duration and extent of snow cover in the Arctic. Decline in seasonal sea ice coverage along the majority of the Arctic coastline in recent decades is projected to continue, contributing to an increase in coastal hazards (including open water storm surge, coastal erosion and flooding). {2.3.2, 3.4.2, 3.4.3, 9.4.1, 9.4.2, 9.5, 12.4.6, 12.4.9, Atlas.11.2}

Coastal and oceanic: Higher sea levels contribute to *high confidence* for projected increases of Arctic coastal flooding and higher coastal erosion (aided by sea ice loss) (*medium confidence*), with lower confidence for those regions with substantial land uplift (Arctic Northeast North America and Greenland). {12.4.9.5}

TS.4.3.2.9 Ocean

The Indian Ocean, western equatorial Pacific Ocean and western boundary currents have warmed faster than the global average (*very high confidence*), with the largest changes in the frequency of marine heatwaves (MHWs) projected in the western tropical Pacific and the Arctic Ocean (*medium confidence*). The Pacific and Southern Ocean are projected to freshen and the Atlantic to become more saline (*medium confidence*). Anthropogenic warming is *very likely* to further decrease ocean oxygen concentrations, and this deoxygenation is expected to persist for thousands of years (*medium confidence*). Arctic sea ice losses are projected to continue, leading to a practically ice-free Arctic in September by the end of the 21st century under high CO_2 emissions scenarios (*high confidence*). {2.3, 5.3, 9.2, 9.3, Box 9.2, 12.4.8}

In addition to the main changes summarized above and in TS.4.3.1, further details are given below.

Ocean surface temperature: The Southern Ocean, the eastern equatorial Pacific, and the North Atlantic Ocean have warmed more slowly than the global average or slightly cooled. Global warming of 2°C above 1850–1900 levels would result in the exceedance of numerous hazard thresholds for pathogens, seagrasses, mangroves, kelp forests, rocky shores, coral reefs and other marine ecosystems (*medium confidence*). {9.2.13, 12.4.8}

Marine heatwaves: Moderate increases in MHW frequency are projected for mid-latitudes, and only small increases are projected for the Southern Ocean (*medium confidence*). Under the SSP5-8.5 scenario, permanent MHWs (more than 360 days per year) are projected to occur in the 21st century in parts of the tropical ocean, the Arctic Ocean and around 45°S; however, the occurrence of such permanent MHWs can be largely avoided under SSP1-2.6 scenario. {Box 9.2, 12.4.8}

Ocean acidity: With the rising CO_2 concentration, the ocean surface pH has declined globally over the past four decades (*virtually certain*). {2.3.3.5, 5.3.3.2, 12.4.8}

Ocean salinity: At the basin scale, it is *very likely* that the Pacific and the Southern Ocean have freshened while the Atlantic has become more saline. {2.3.3.2, 9.2.2.2, 12.4.8}

Dissolved oxygen: In recent decades, low oxygen zones in ocean ecosystems have expanded. {2.3.4.2, 5.3.3.2, 12.4.8}

Sea ice: Arctic perennial sea ice is being replaced by thin, seasonal ice, with earlier spring melt and delayed fall freeze up. There is no clear trend in the Antarctic sea ice area over the past few decades and l*ow confidence* in its future change. {2.3.2.1.1, 9.3.1.1, 12.4.8, 12.4.9}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

TS.4.3.2.10 Other Typological Domains

Some types of regions found in different continents face common climate challenges regardless of their location. These include biodiversity hot spots that will *very likely* see even more extreme heat and droughts, mountain areas where a projected raising in the freezing level height will alter snow and ice conditions (*high confidence*), and tropical forests that are increasingly prone to fire weather (*medium confidence*). {Box 8.2, 8.4, 9.5, 12.3, 12.4}

Biodiversity hotspots located around the world will each face unique challenges in CID changes. Heat, drought and length of dry season, wildfire weather, sea surface temperature and deoxygenation are relevant drivers to terrestrial and freshwater ecosystems and have marked increasing trends. {12.3, 12.4.10.1}

Desert and semi-arid areas are strongly affected by CIDs such as extreme heat, drought and dust storms, with large-scale aridity trends contributing to expanding drylands in some regions (*high confidence*). {12.3, 12.4.10.3}

Average warming in mountain areas varies with elevation, but the pattern is not globally uniform (*medium confidence*). Extreme precipitation is projected to increase in major mountainous regions (*medium* to *high confidence* depending on location), with potential cascading consequences of floods, landslides and lake outbursts in all scenarios (*medium confidence*). {Box 8.2, 8.4.1.5, 9.5.1.3, 9.5.3.3, 9.5.2.3, Cross-Chapter Box 10.4, 11.5.5, 12.3, 12.4.1–12.4.6, 12.4.10.4}

Most tropical forests are challenged by a mix of emerging warming trends that are particularly large in comparison to historical variability (*medium confidence*). Water cycle changes bring prolonged drought, longer dry seasons, and increased fire weather to many tropical forests (*medium confidence*). {10.5, 12.3, 12.4}

[START BOX TS.14 HERE]

Box TS.14: Urban Areas

With global warming, urban areas and cities will be affected by more frequent occurrence of extreme climate events, such as heatwaves, with more hot days and warm nights as well as sea level rise and increases in tropical cyclone storm surge and rainfall intensity that will increase the probability of coastal city flooding (*high confidence*). {Box 10.3, 11.3, 11.5, 12.3, 12.4}

Urban areas have special interactions with the climate system, for instance in terms of heat islands and altering the water cycle, and thereby will be more affected by extreme climate events such as extreme heat (*high confidence*). With global warming, increasing relative sea level compounded by increasing tropical cyclone storm surge and rainfall intensity will increase the probability of coastal city flooding (*high confidence*). Arctic coastal settlements are particularly exposed to climate change due to sea ice retreat (*high confidence*). Improvements in urban climate modelling and climate monitoring networks have contributed to understanding the mutual interaction between regional and urban climate (*high confidence*). {Box 10.3, 11.3, 11.5, 12.3, 12.4}

Despite having a negligible effect on global surface temperature (*high confidence*), urbanization has exacerbated the effects of global warming through its contribution to the observed warming trend in and near cities, particularly in annual mean minimum temperature (*very high confidence*) and increases in mean and extreme precipitation over and downwind of the city, especially in the afternoon and early evening (*medium confidence*). {2.3, Box 10.3, 11.3, 11.4, 12.3, 12.4}

Combining climate change projections with urban growth scenarios, future urbanization will amplify (*very high confidence*) the projected local air temperature increase, particularly by strong influence on minimum temperatures, which is approximately comparable in magnitude to global warming (*high confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Compared to present day, large implications are expected from the combination of future urban development and more frequent occurrence of extreme climate events, such as heatwaves, with more hot days and warm nights adding to heat stress in cities (*very high confidence*). {Box 10.2, 11.3, 12.4}

Both sea levels and air temperatures are projected to rise in most coastal settlements (*high confidence*). There is *high confidence* in an increase in pluvial flood potential in urban areas where extreme precipitation is projected to increase, especially at high global warming levels. {11.4, 11.5, 12.4}

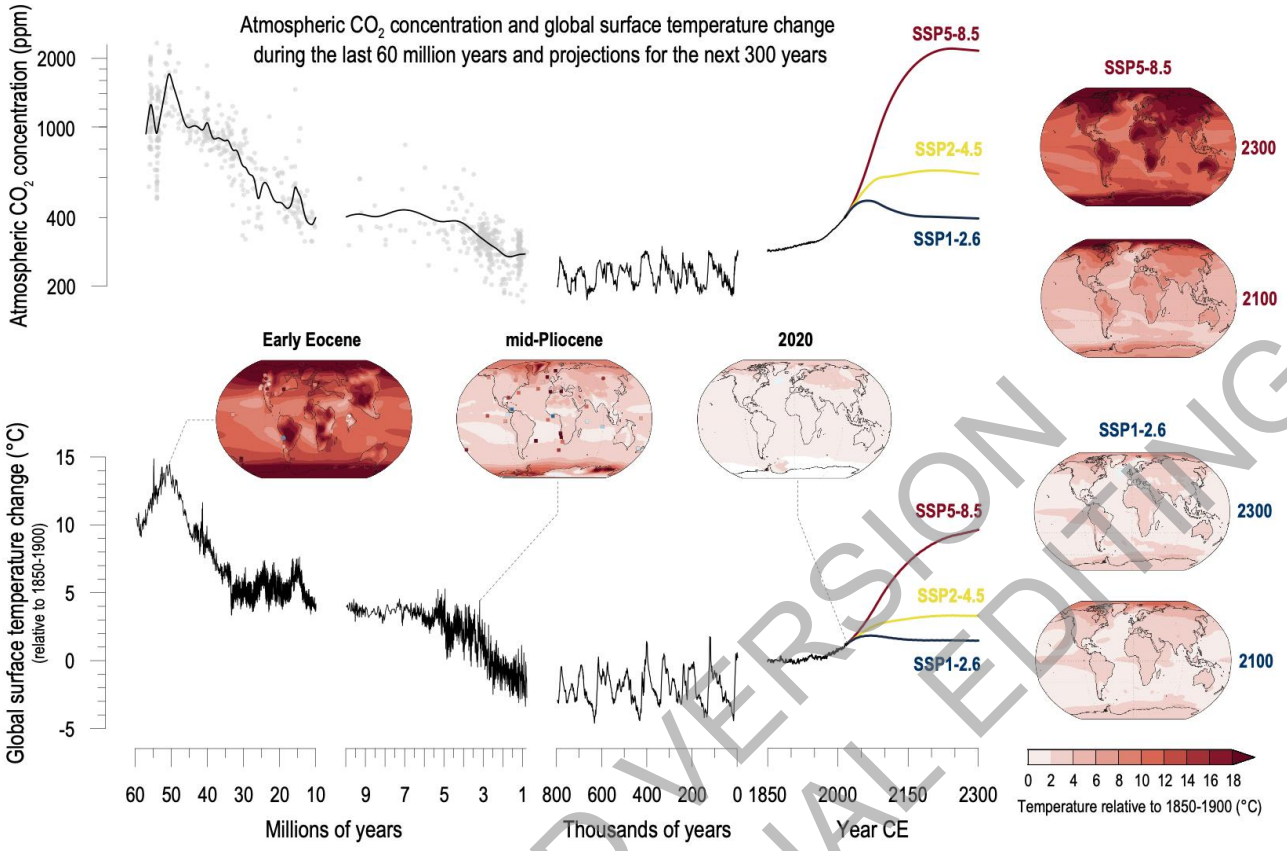
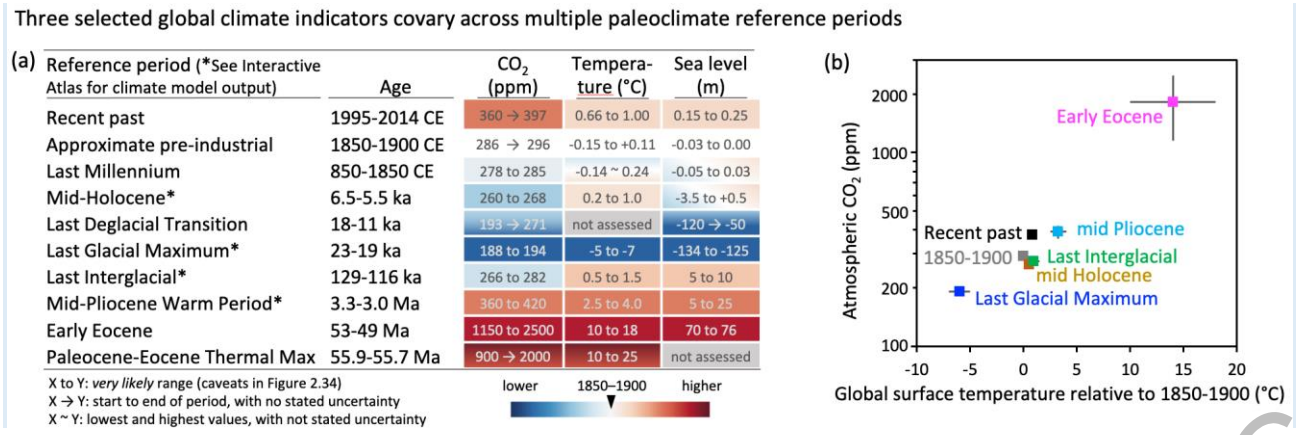
Figures





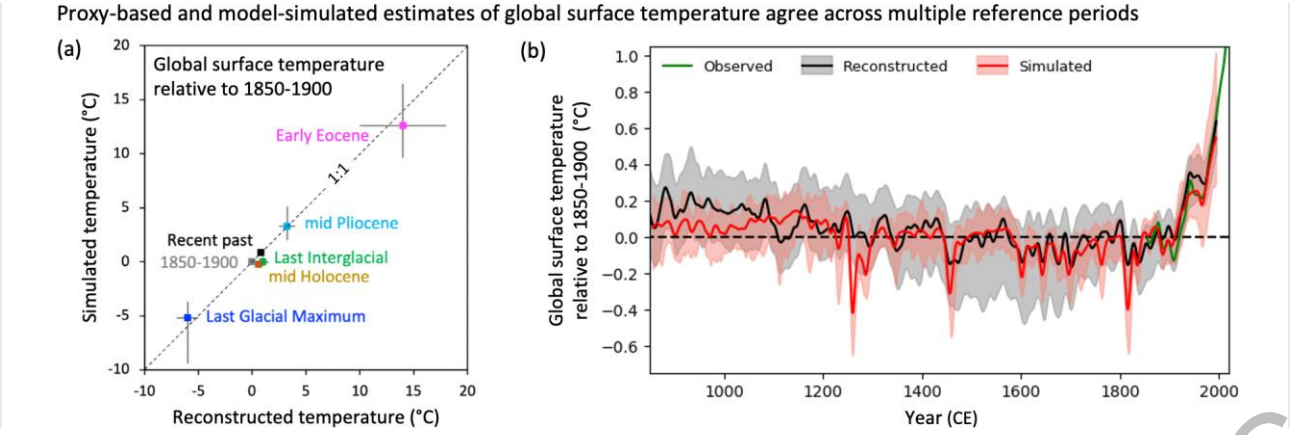


Figure TS.1: Changes in atmospheric CO_2 and global surface temperature (relative to 1850-1900) from the deep past to the next 300 years. *The intent is to show that CO_2 and temperature covary, both in the past and into the future, and that projected CO_2 and temperatures are similar to those only from many millions of years ago.* CO_2 concentrations from millions of years ago are reconstructed from multiple proxy records (grey dots are data from 2.2.3.1, Figure 2.3 shown with cubic-spline fit). CO_2 levels for the last 800,000 years through the mid-20th century are from air trapped in polar ice; recent values are from direct air measurements (Figure TS.9). {1.2.1.2, 2.2.3, Figures 1.5, 2.4, 2.5} Global surface temperature prior to 1850 is estimated from marine oxygen isotopes, one of multiple sources of evidence used to assess paleo temperatures in this report. {2.3.1.1.1, Cross-Chapter Box 2.1, Figure 1} Temperature of the past 170 years is the AR6 assessed mean (Cross-Section Box TS.1). {2.3.1.1} CO_2 levels and global surface temperature change for the future are shown for three SSP scenarios (TS.1.3) through 2300 CE, using Earth System Model emulators calibrated to the assessed global surface temperatures. {4.7.1, Cross-Chapter Box 7.1} Their smooth trajectories do not account for inter-annual to inter-decadal variability, including transient response to potential volcanic eruptions. {Cross-Chapter Box 4.1} Global maps for two paleo reference periods are based on CMIP6 and pre-CMIP6 multi-model means, with site-level proxy data for comparison (squares and circles are marine and terrestrial, respectively) (Box TS.2). {Cross-Chapter Box 2.1, Figure 7.13} The map for 2020 is an estimate of the total observed warming since 1850-1900. {Figure 1.14} Global maps at right show two SSP scenarios at 2100 (2081-2100) {4.5.1} and at 2300 (2281-2300; map from CMIP6 models; temperature assessed in 4.7.1). A brief account of the major climate forcings associated with past global temperature changes is in Cross-Chapter Box 2.1.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Box TS.2, Figure 1: Paleoclimate and recent reference periods, with selected key indicators. *The intent of this figure is to list the paleoclimate reference periods used in the WGI report, to summarize three key global climate indicators, and compare CO_2 with global temperature over multiple periods.* (a) Three large-scale climate indicators (atmospheric CO_2, global surface temperature relative to 1850-1900, and global mean sea level relative to 1900), based on assessments in Chapter 2, with confidence levels ranging from *low* to *very high*. (b) Comparison between global surface temperature (relative to 1850-1900) and atmospheric CO_2 concentration for multiple reference periods (mid-points with 5–95% ranges). {2.2.3, 2.3.1.1, 2.3.3.3, Figure 2.34}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Box TS.2, Figure 2: Global surface temperature as estimated from proxy records (reconstructed) and climate models (simulated). *The intent of this figure is to show the agreement between observations and models of global temperatures during paleo reference periods*. (a) For individual paleoclimate reference periods. (a) For individual paleoclimate reference periods. (b) For the last millennium, with instrumental temperature (AR6 assessed mean,10-year smoothed). Model uncertainties in (a) and (b) are 5-95% ranges of multi-model ensemble means; reconstructed uncertainties are 5-95% ranges (*medium confidence*) of (a) midpoints and (b) multi-method ensemble median. {2.3.1.1, Figure 2.34, Figure 3.2c, Figure 3.44}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

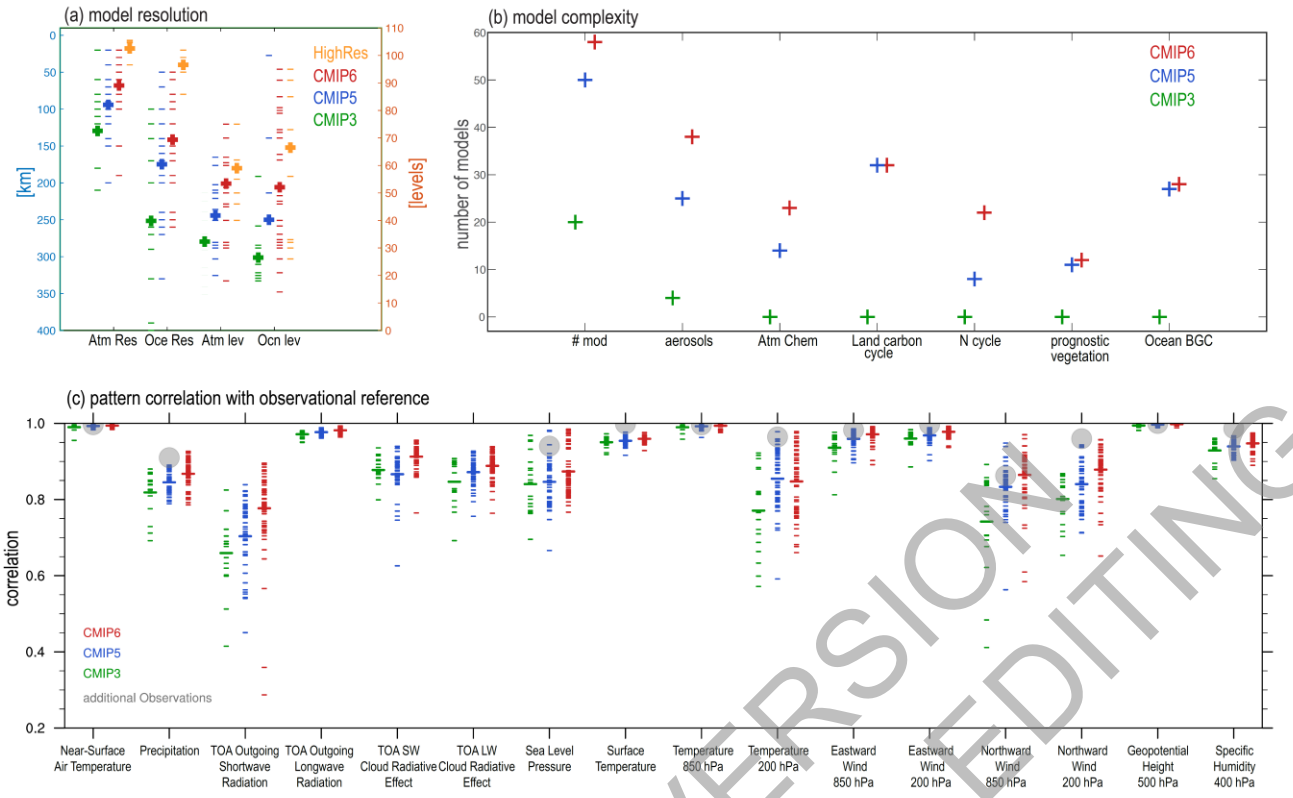

Figure TS.2: **Progress in climate models.** *The intent is to show present improvements in climate models in resolution, complexity and representation of key variables.* (a) Evolution of model horizontal resolution and vertical levels (based on Figure 1.19); (b) Evolution of inclusion of processes and resolution from CMIP Phase 3 (CMIP3) to CMIP6 (Annex II). (c) Centred pattern correlations between models and observations for the annual mean climatology over the period 1980–1999. Results are shown for individual CMIP3 (cyan), CMIP5 (blue) and CMIP6 (red) models (one ensemble member is used) as short lines, along with the corresponding ensemble averages (long lines). The correlations are shown between the models and the primary reference observational data set (from left to right: ERA5, GPCP-SG, CERES-EBAF, CERES-EBAF, CERES-EBAF, CERES-EBAF, JR-55, ERA5, ERA5, ERA5, ERA5, ERA5, ERA5, AIRS, ERA5, ESACCI-Soilmoisture, LAI3g, MTE). In addition, the correlation between the primary reference and additional observational data sets (from left to right: NCEP, GHCN, -, -, -, -, ERA5, HadISST, NCEP, NCEP, NCEP, NCEP, NCEP, NCEP, ERA5, NCEP, -, -, FLUXCOM) are shown (solid grey circles) if available. To ensure a fair comparison across a range of model resolutions, the pattern correlations are computed after regridding all datasets to a resolution of 4º in longitude and 5º in latitude. (Expanded from Figure 3.43; produced with ESMValTool version 2).

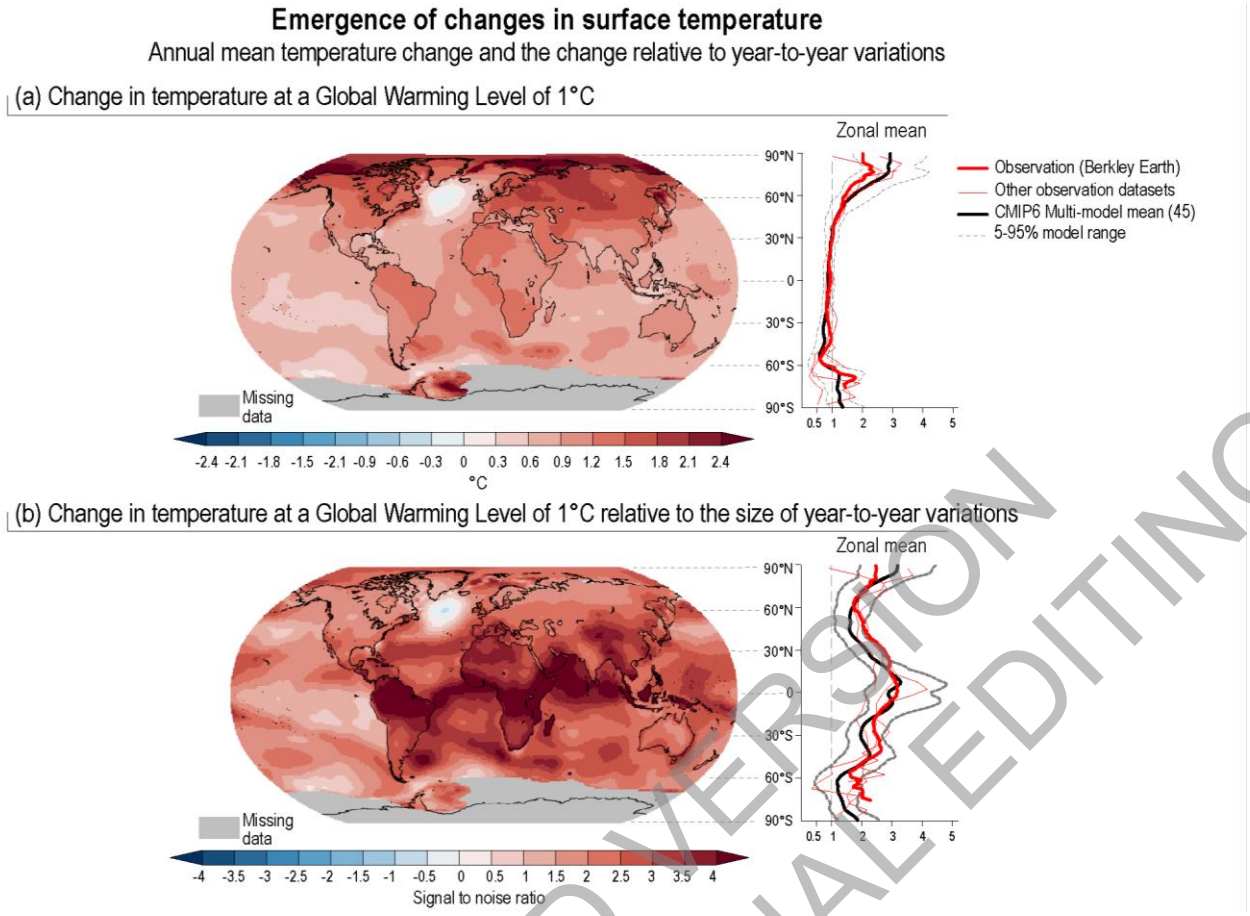
ACCEPTED VERSION. SUBJECT TO FINAL EDITING



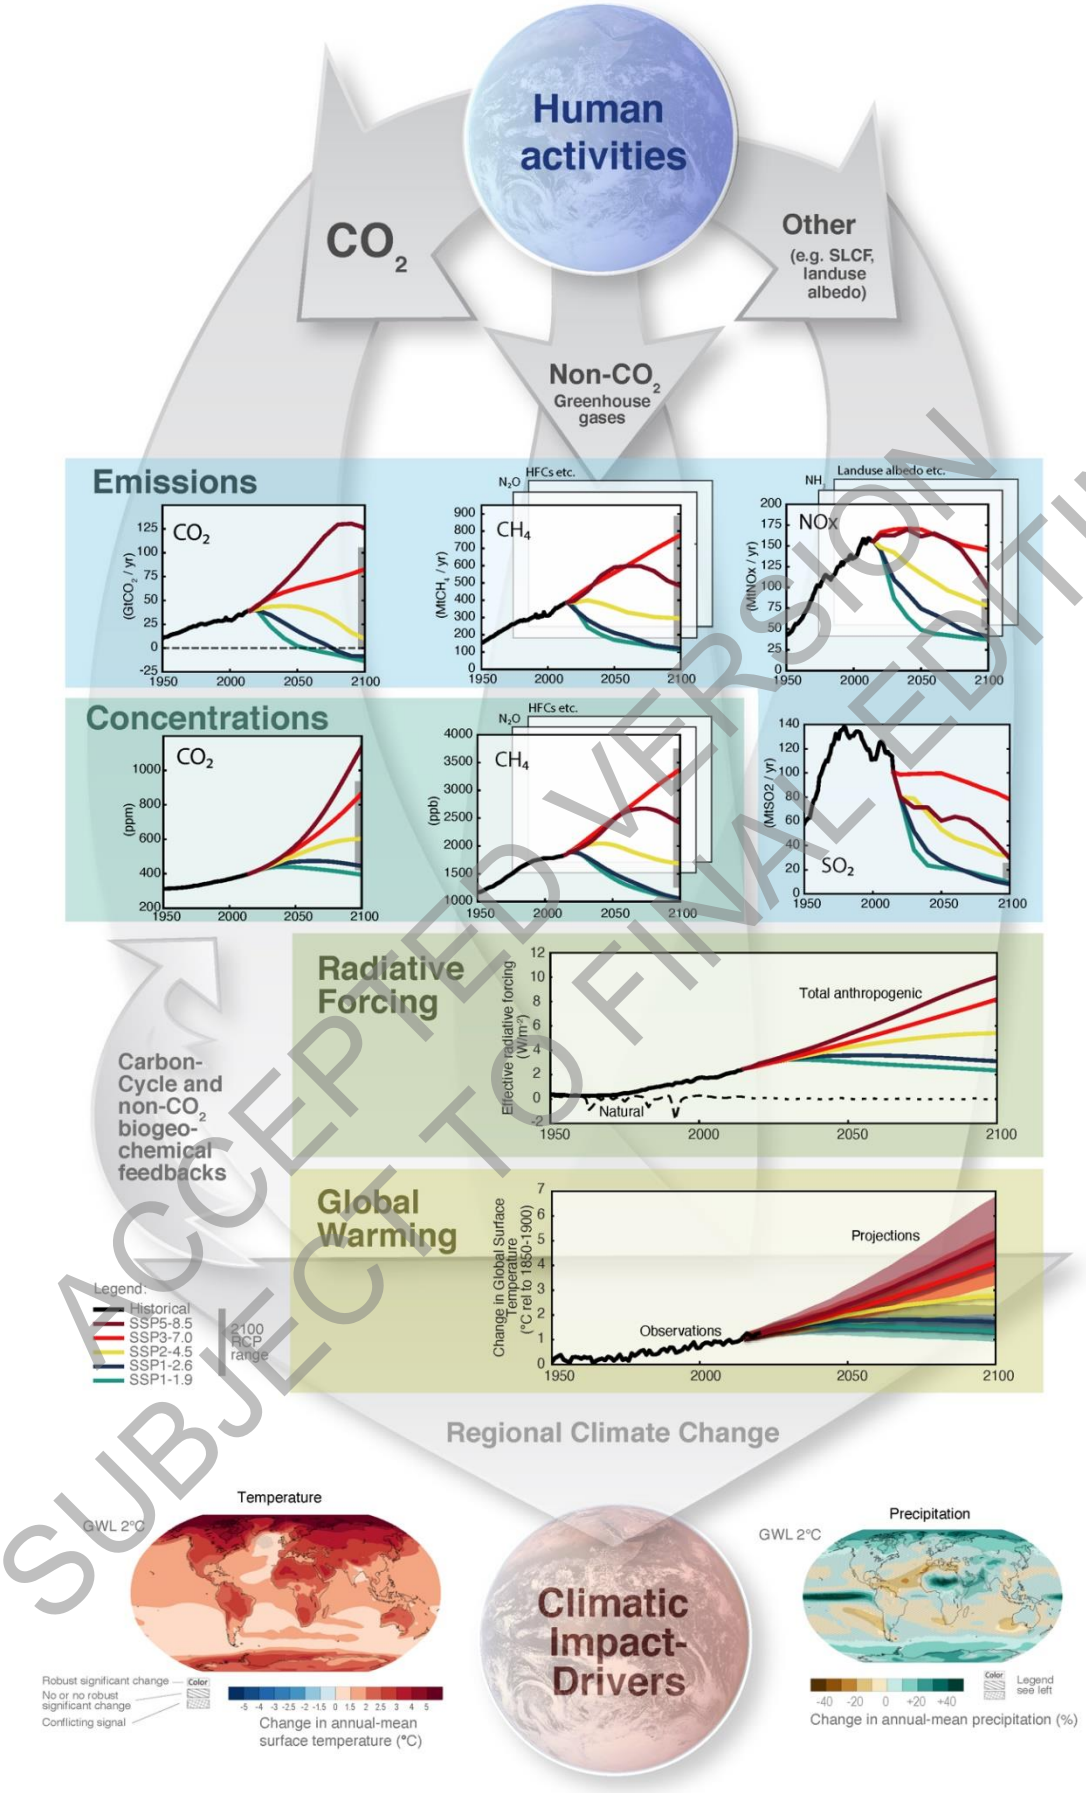


Figure TS.3: **Emergence of changes in temperature over the historical period.** *The intent of this figure is to show how observed changes in temperature have emerged and that the emergence pattern agrees with model simulations.* The observed change in temperature at a global warming level of 1°C (top map), and the signal-to-noise ratio (the change in temperature at a global warming level of 1°C, divided by the size of year-to-year variations, bottom map) using data from Berkeley Earth. The right panels show the zonal means of the maps and include data from different observational datasets (red) and the CMIP6 simulations (black, including the 5-95% range) processed in the same way as the observations. {1.4.2, 10.4.3}

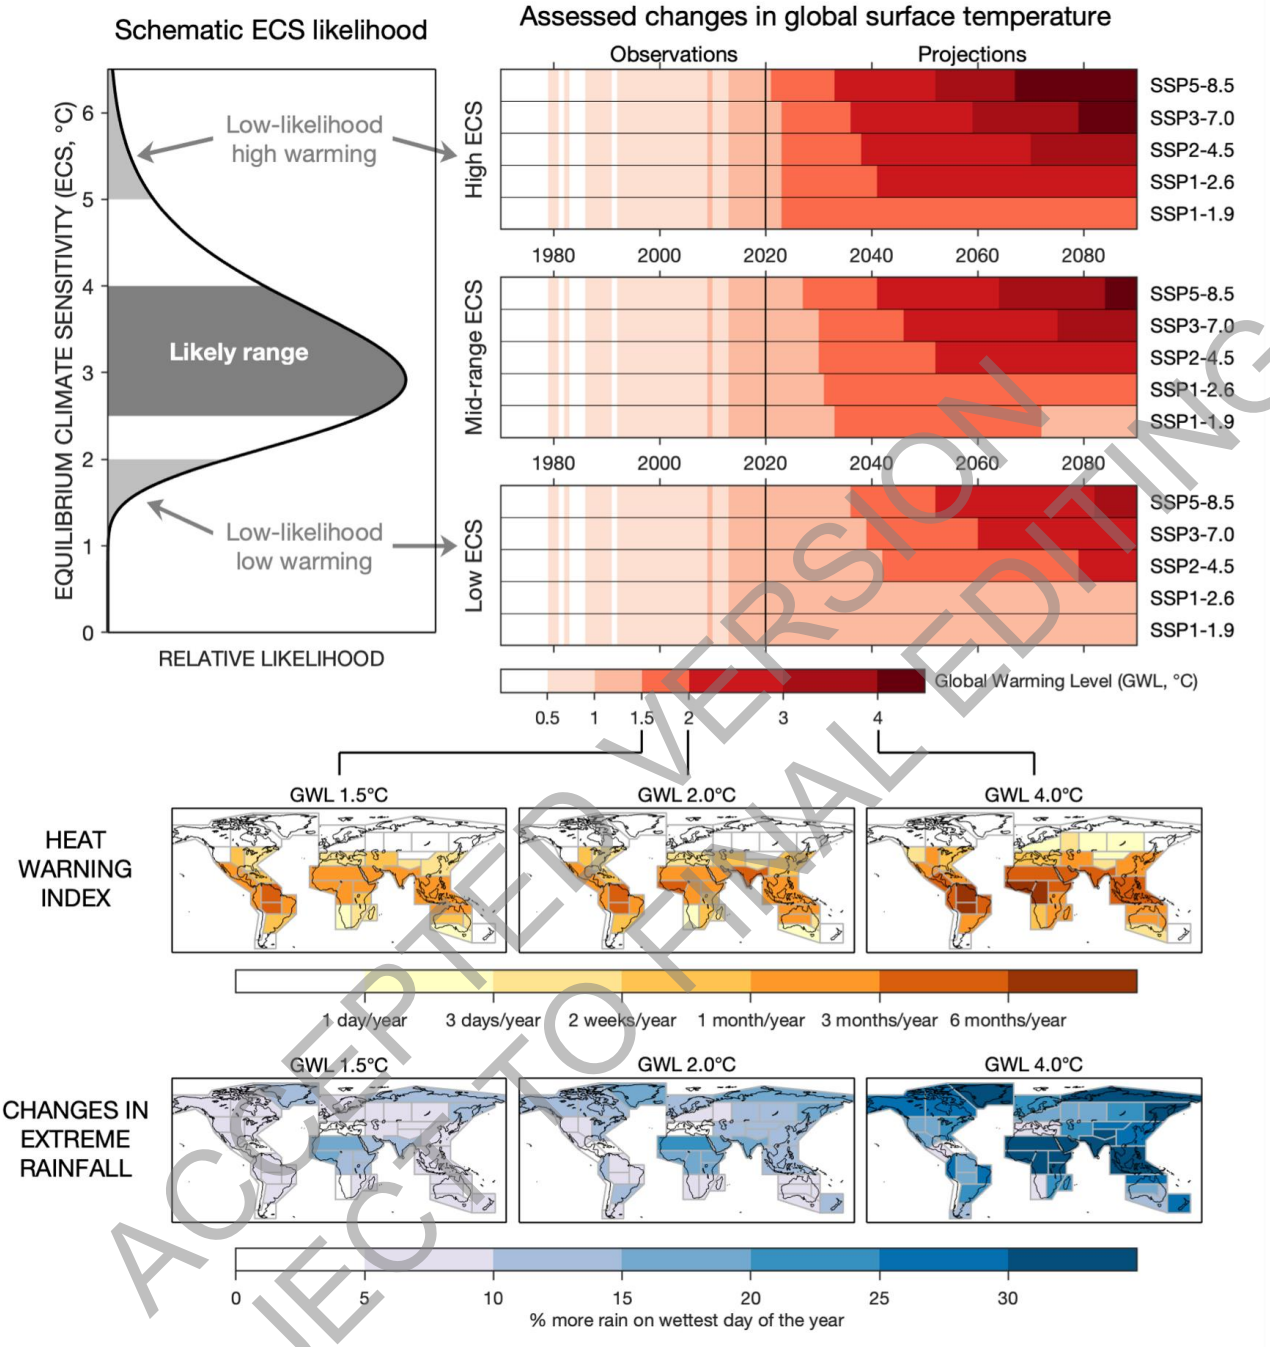
Figure TS.5: **How scenarios are linked to global warming levels (GWLs), and examples of the evolution of patterns of change with global warming levels.** Left: Illustrative example of GWLs defined as global surface temperature response to anthropogenic emissions in unconstrained CMIP6 simulations, for two illustrative scenarios (SSP1-2.6 and SSP3-7.0). The time when a given simulation reaches a GWL, e.g., +2°C, relative to 1850-1900 is taken as the time when the central year of a 20-year running mean first reaches that level of warming. See the dots for +2°C, and how not all simulations reach all levels of warming. The assessment of the timing when a GWL is reached takes into account additional lines of evidence and is discussed in Cross-Section Box TS.1. Right: Multi-model, multi-simulation average response patterns of change in near-surface air temperature, precipitation (expressed as percentage change) and soil moisture (expressed in standard deviations of interannual variability), for three GWLs. The number to the top right of the panels shows the number of model simulations averaged across including all models that reach the corresponding GWL in any of the 5 SSPs. See TS.2 for discussion. (See also Cross-Chapter Box 11.1)

ACCEPTED VERSION SUBJECT TO FINAL EDITING



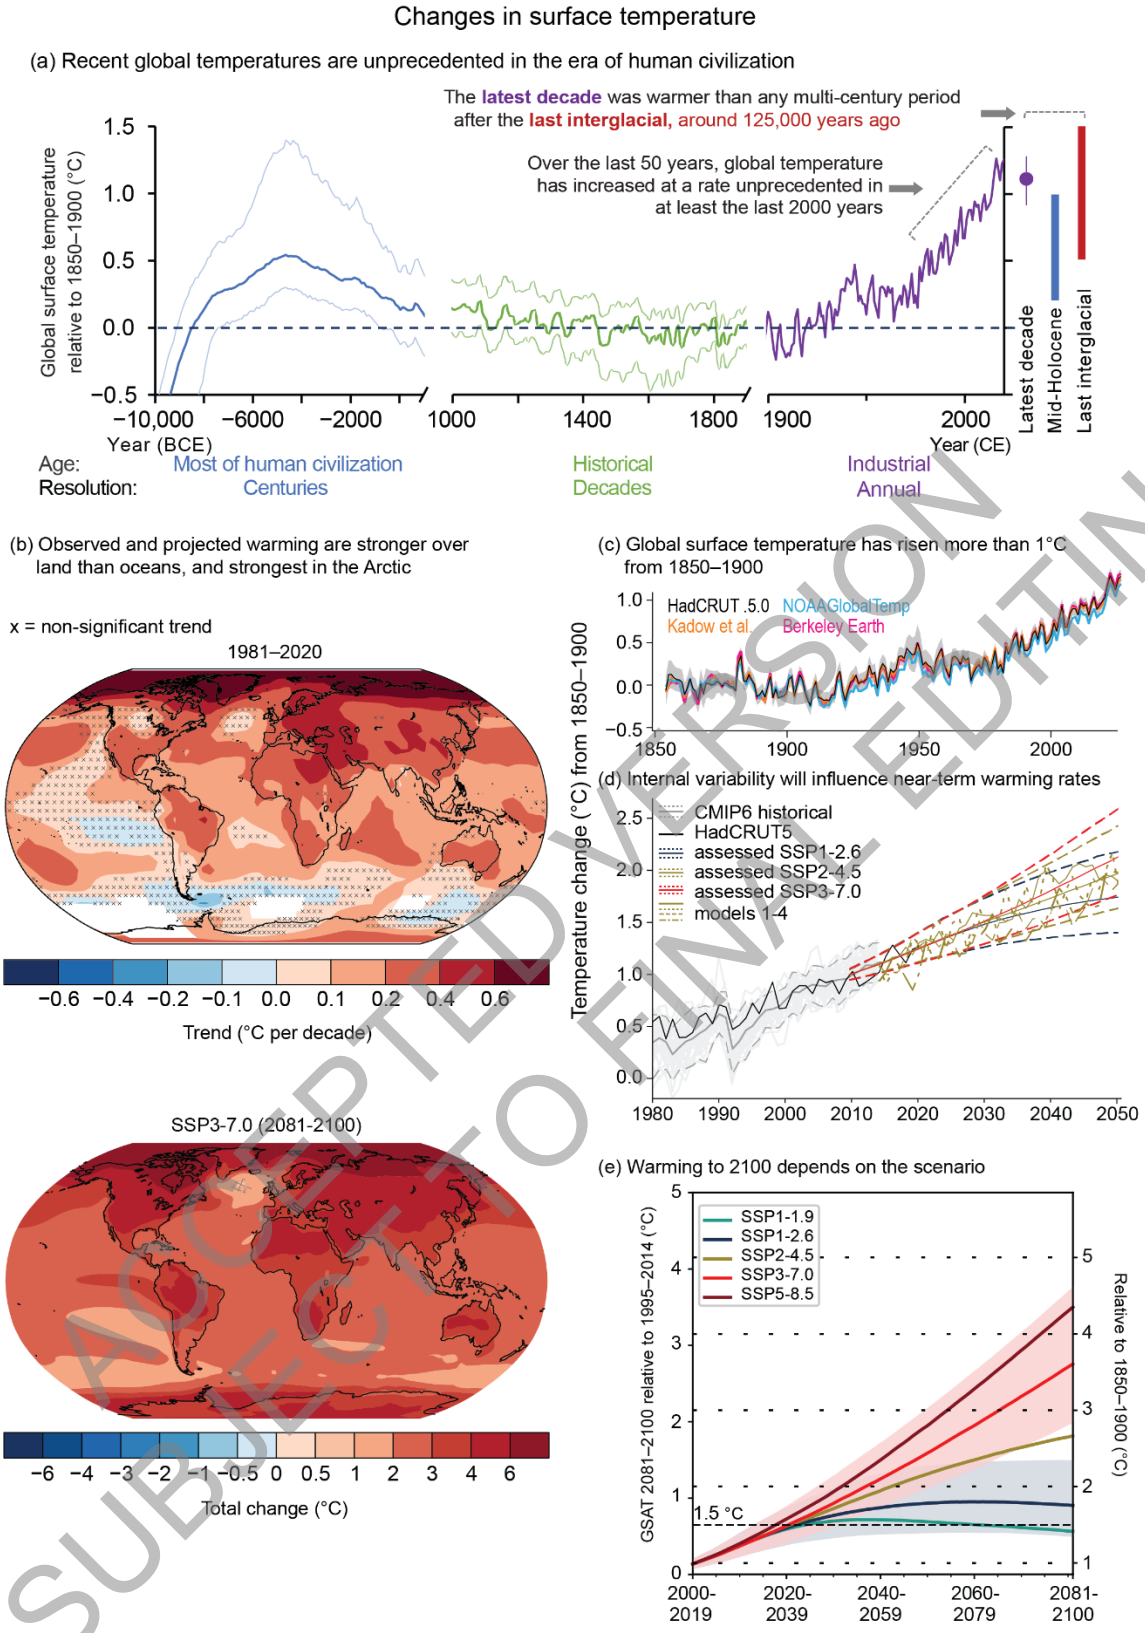


Figure TS.6: **A graphical abstract for key aspects of the Technical Summary related to observed and projected changes in global surface temperature and associated regional changes in climatic impact-drivers relevant for impact and risk assessment.** Top left: a schematic representation of the likelihood for equilibrium climate sensitivity (ECS), consistent with the AR6 assessment (see Chapter 7; TS.3). ECS values above 5°C and below 2°C are termed low-likelihood high warming (LLHW) and low-likelihood low warming, respectively. Top right: Observed (see Cross-Section Box TS.1) and projected global surface temperature changes, shown as global warming levels (GWL) relative to 1850-1900, using the assessed 95% (top), 50% (middle) and 5% (bottom) likelihood time series (see Chapter 4; TS.2). Bottom panels show maps of CMIP6 median projections of two climatic impact-drivers (CIDs) at three different GWLs (columns for 1.5, 2 and 4°C) for the AR6 land regions (see Chapters 1, 10, Atlas; TS.4). The heat warning index is the number of days per year averaged across each region at which a heat warning for human health at level 'danger' would be issued according to the U.S. National Oceanic and Atmospheric Administration (NOAA) (NOAA HI41, see Chapter 12

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and Technical Annex VI). The maps of extreme rainfall changes show the percentage change in the amount of rain falling on the wettest day of a year (Rx1day, relative to 1995-2014, see Chapter 11) averaged across each region when the respective GWL is reached. Additional CIDs are discussed in TS.4.

Cross-Section Box TS.1, Figure 1: Earth's surface temperature history and future with key findings annotated within each panel. *The intent of this figure is to show global surface temperature observed changes from the Holocene to now, and projected changes.* (a) Global

surface temperature over the Holocene divided into three time scales. (i) 12,000 to 1000 years ago (10,000 BCE to 1000 CE) in 100-year time steps, (ii) 1000 to 1900 CE, 10-year smooth, and (iii) 1900 to 2020 CE (mean of four datasets in panel (c)). Median of the multi-method reconstruction (bold lines), with 5% and 95% percentiles of the ensemble members (thin lines). Vertical bars are 5th to 95th percentile ranges of estimated global surface temperature for the Last Interglacial and mid Holocene (*medium confidence*) (Section 2.3.1.1). All temperatures relative to 1850–1900. (b) Spatially resolved trends (°C per decade) for (upper map) HadCRUTv5 over 1981–2020, and (lower map, total change) multi-model mean projected changes from 1995–2014 to 2081–2010 in the SST3-7.0 scenario. Observed trends have been calculated where data are present in both the first and last decade and for at least 70% of all years within the period using OLS. Significance is assessed with AR(1) correction and denoted by stippling. Hatched areas in the lower map show areas of conflicting model evidence on significance of changes. (c) Temperature from instrumental data for 1850–2020, including annually resolved averages for the four global surface temperature datasets assessed in Section 2.3.1.1.3 (see text for references). The grey shading shows the uncertainty associated with the HadCRUTv5 estimate. All temperatures relative to the 1850–1900 reference period. (d) Recent past and 2015–2050 evolution of annual mean global surface temperature change relative to 1850–1900, from HadCRUTv5 (black), CMIP6 historical simulations (up to 2014, in grey, ensemble mean solid, 5% and 95% percentiles dashed, individual models thin), and CMIP6 projections under scenario SSP2-4.5, from four models that have an equilibrium climate sensitivity near the assessed central value (thick yellow). Solid thin coloured lines show the assessed central estimate of 20-year change in global surface temperature for 2015–2050 under three scenarios, and dashed thin coloured lines the corresponding 5% and 95% quantiles. (e) Assessed projected change in 20-year running mean global surface temperature for five scenarios (central estimate solid, *very likely* range shaded for SSP1-2.6 and SSP3-7.0), relative to 1995–2014 (left y-axis) and 1850–1900 (right y-axis). The y-axis on the right-hand side is shifted upward by 0.85°C, the central estimate of the observed warming for 1995–2014, relative to 1850–1900. The right y-axis in (e) is the same as the y-axis in (d).

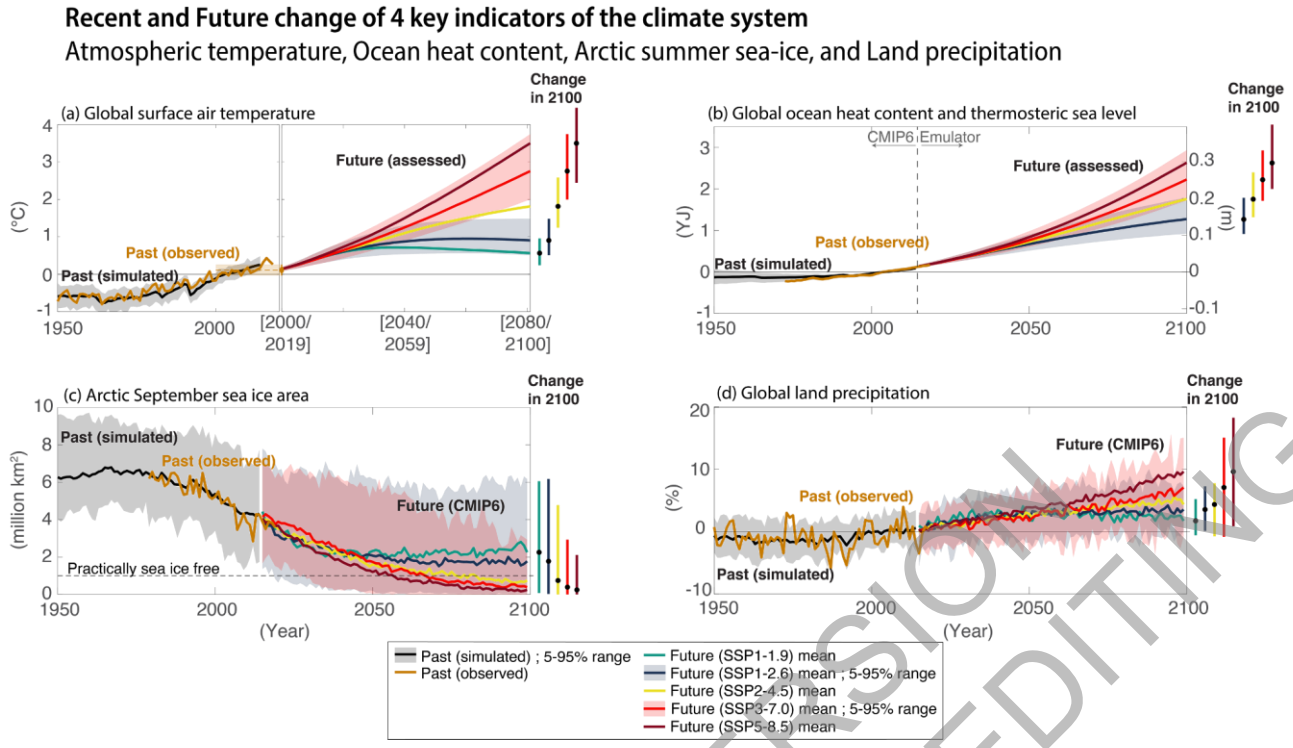
Figure TS.7: **Simulated and observed changes compared to the 1995–2014 average in key large-scale indicators of climate change across the climate system, for continents, ocean basins and globally up to 2014.** Black lines show observations, orange lines and shading show the multi-model mean and 5–95th percentile ranges for CMIP6 historical simulations including anthropogenic and natural forcing, and green lines and shading show corresponding ensemble means and 5-95th percentile ranges for CMIP6 natural-only simulations. Observations after 2014 (including, for example, a strong

subsequent decrease of Antarctic sea-ice area that leads to no significant overall trend since 1979) are not shown because the CMIP6 historical simulations end in 2014. A 3-year running mean smoothing has been applied to all observational time series. {3.8, Figure 3.41}

ACCEPTED VERSION
SUBJECT TO FINAL EDITING



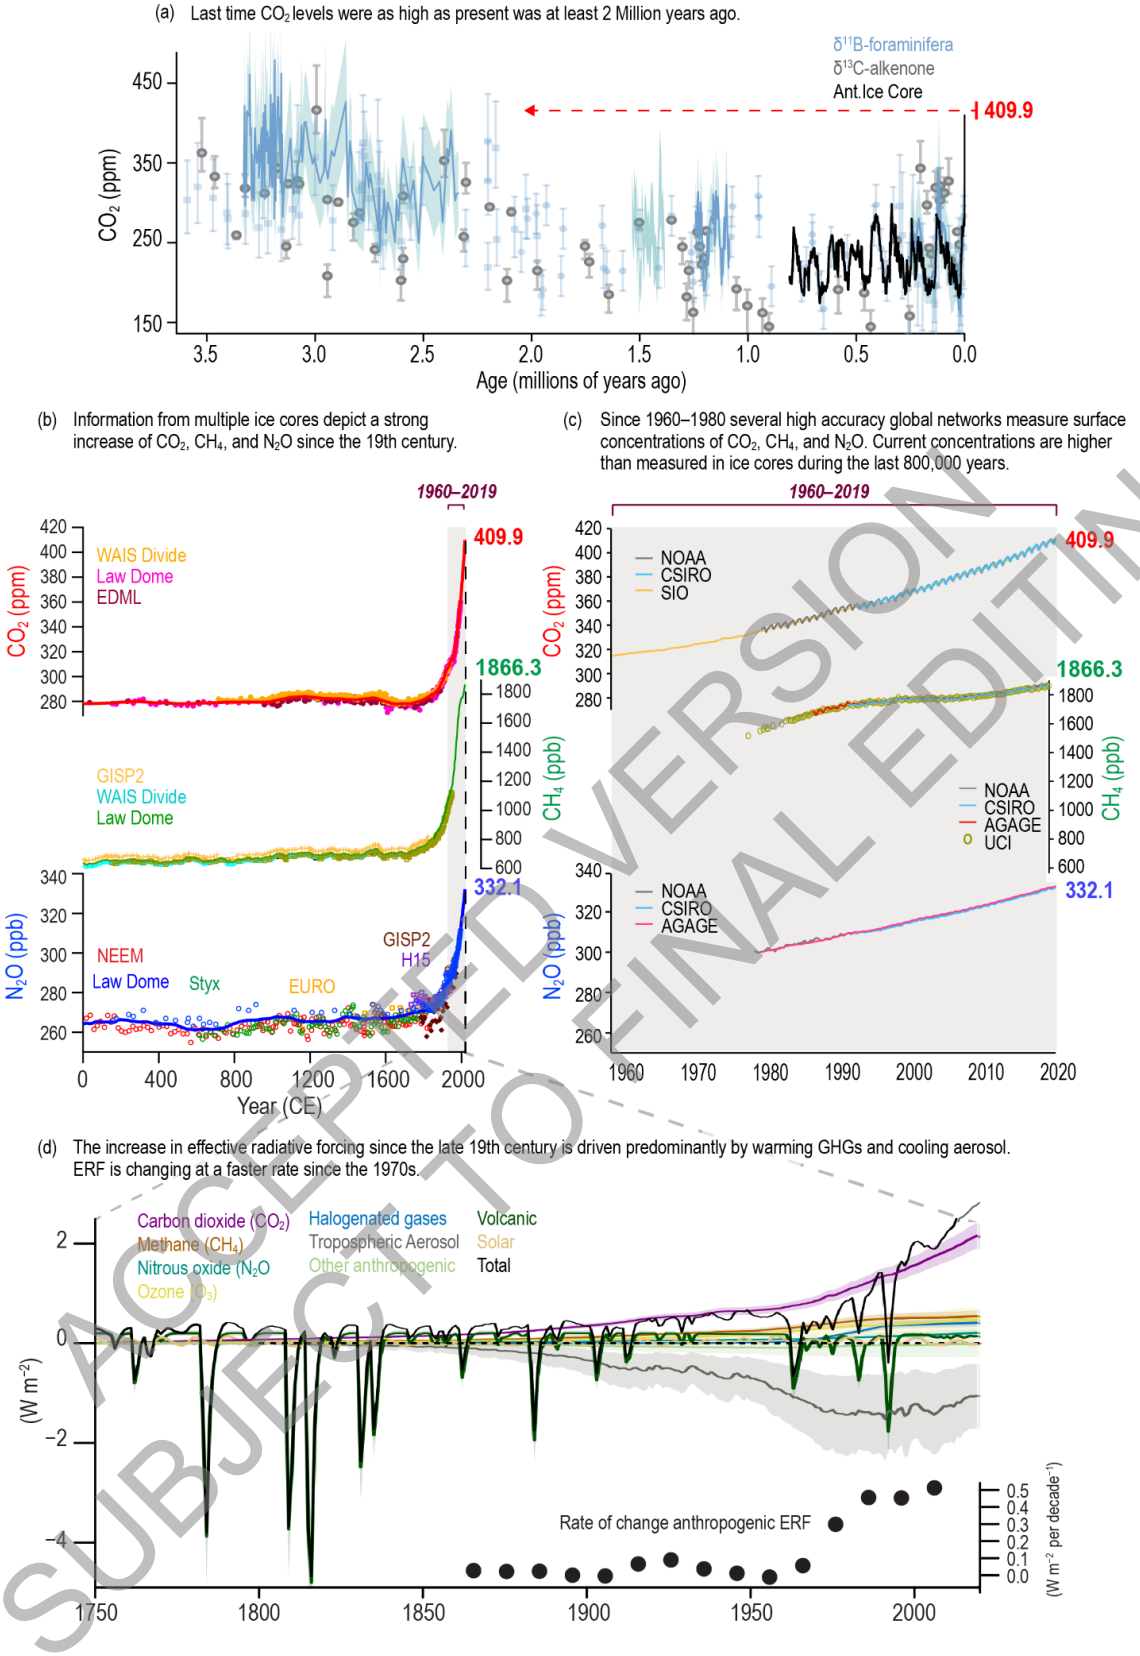


Figure TS.8: **Observed, simulated and projected changes compared to the 1995–2014 average in 4 key indicators of the climate system through to 2100 differentiated by SSP scenario pathway.** Past simulations are based on the CMIP6 multi-model ensemble. Future projections are based on the assessed ranges based upon multiple lines of evidence for (a) global surface temperature (Cross-Section Box TS.1) and (b) global ocean heat content and the associated thermosteric sea level contribution to Global Mean Sea Level (GMSL) change (right-hand axis) using a climate model emulator (Cross-Chapter Box 7.1), and CMIP6 simulations for (c) Arctic September sea ice and (d) Global land precipitation. SSP1-1.9 and SSP1-2.6 projections show that reduced GHG emissions lead to a stabilization of global surface temperature, Arctic sea ice area and global land precipitation over the 21st century. SSP1-2.6 shows that emissions reductions have the potential to substantially reduce the increase in ocean heat content and thermosteric sea level rise over the 21st century but that some increase is unavoidable. {4.3, 9.3, 9.6, Figure 4.2, Figure 9.6}

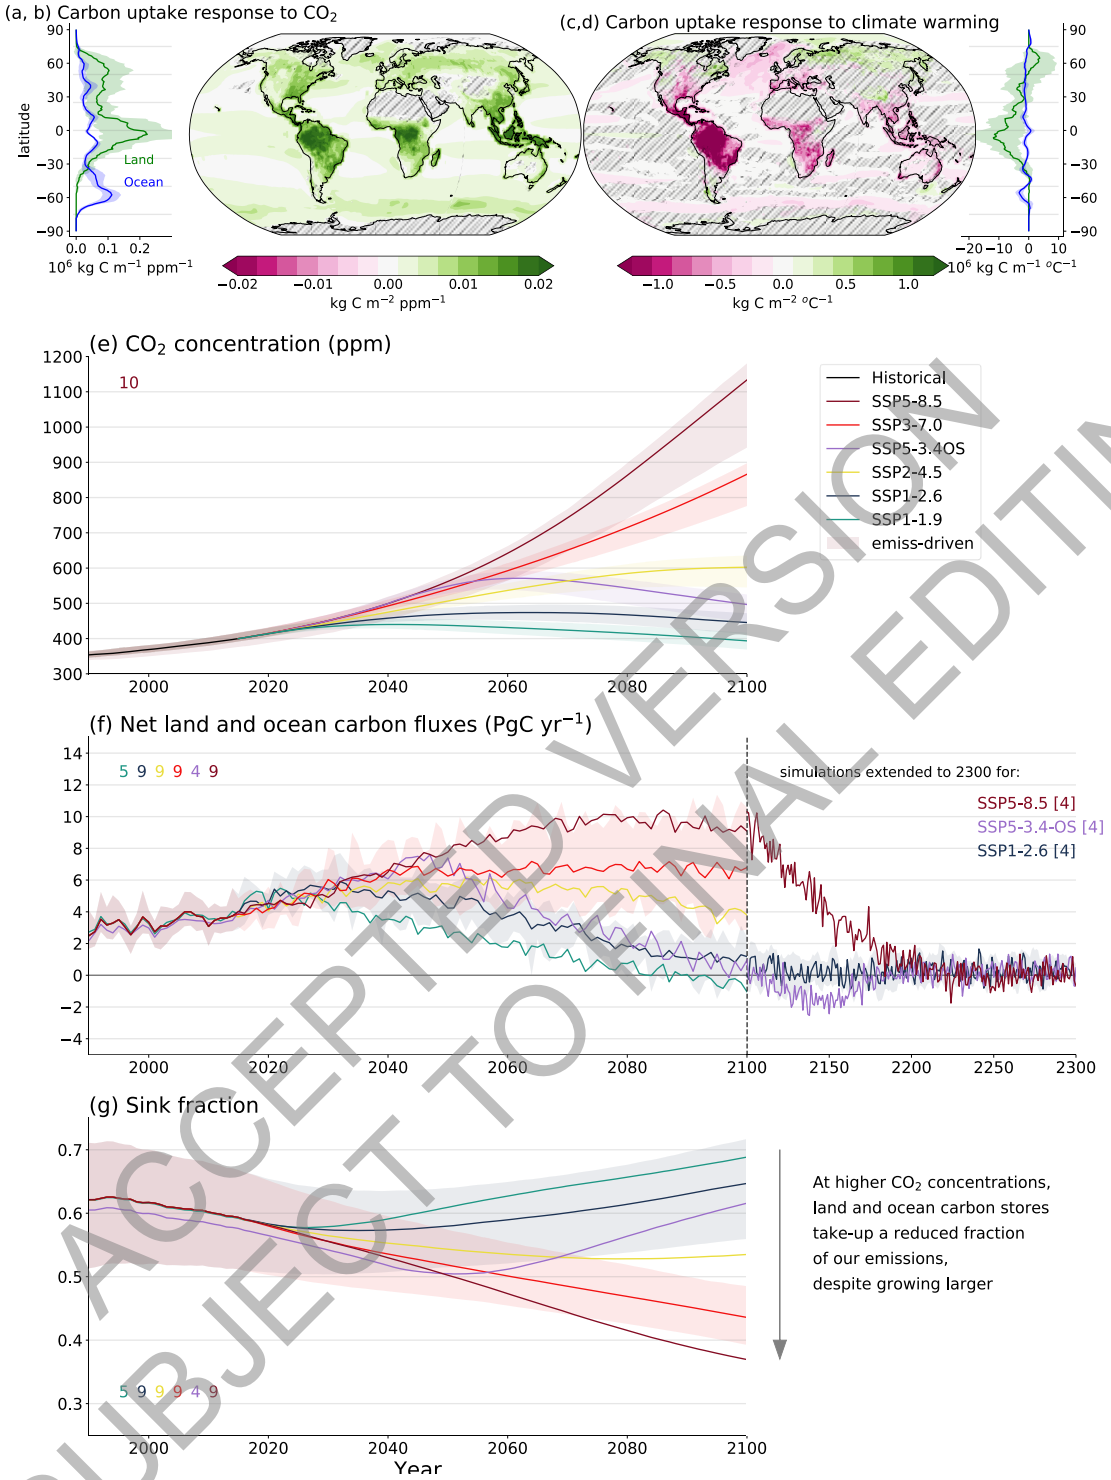
Figure TS.11: **Past and future ocean and ice sheet changes.** Observed and simulated historical changes and projected future changes under varying greenhouse gas emissions scenarios. Simulated and projected ocean changes are shown as CMIP6 ensemble mean, and 5-95% range (shading) is provided for scenario SSP1-2.6 and SSP3-7.0 (except in panel a where range provided for scenario SSP1-2.6 and SSP5-8.5). Mean and 5-95% range in 2100 are shown as vertical bars on the right-hand side of each panel. (a) Change in multiplication factor in surface ocean marine heatwave days relative to 1995-2014 (defined as days exceeding the 99th percentile in SST from 1995-2014 distribution). Assessed observational change span 1982-2019 from AVHRR satellite SST. (b) AMOC transport relative to 1995-2014 (defined as maximum transport at 26°N). Assessed observational change spans 2004-2018 from the RAPID array smoothed with a 12-month running mean (shading around the mean shows the 12-month running standard deviation around the mean). (c) Global mean percent change in ocean oxygen (100–600 m depth), relative to 1995-2014. Assessed observational trends and *very likely* range are from the SROCC assessment, and spans 1970–2010 centered on 2005. (d) Global mean surface pH. Assessed observational change span 1985-2019, from the CMEMS SOCAT-based reconstruction (shading around the global mean shows the 90% confidence interval). (e), (f): Ice sheet mass changes. Projected ice sheet changes are shown as median, 5-95% range (light shading), and 17-83% range (dark shading) of cumulative mass loss and sea level equivalent from ISMIP6 emulation under SSP1-26 and SSP5-85 (shading and bold line), with individual emulated projections as thin lines. Median (dot), 17-83% range (thick vertical bar), and 5-95% range (thin vertical bar) in 2100 are shown as vertical bars on the right-hand side of each panel, from ISMIP6, ISMIP6 emulation, and LARMIP-2. Observation-based estimates: For Greenland (e), for 1972-2018 (Mouginot), for 1992-2016 (Bamber), for 1992-2020 (IMBIE) and total estimated mass loss range for 1840-1972 (Box). For Antarctica (f),

ACCEPTED VERSION SUBJECT TO FINAL EDITING



estimates based on satellite data combined with simulated surface mass balance and glacial isostatic adjustment for 1992-2020 (IMBIE), 1992-2016 (Bamber), and 1979-2017 (Rignot). Left inset maps: mean Greenland elevation changes 2010-2017 derived from CryoSat-2 radar altimetry (e) and mean Antarctica elevation changes 1978-2017 derived from restored analog radar records (f). Right inset maps: ISMIP6 model mean (2093- 2100) projected changes under the MIROC5 climate model for the RCP8.5 scenario. {Box 9.2, 2.3.3, 2.3.4, 3.5.4, 4.3.2, 5.3.2, 5.3.3, 5.6.3, 9.2.3, 9.4.1, 9.4.2, Box 9.2 Figure 1, Figure 9.10, Figure 9.17, Figure 9.18}

Box TS.4, Figure 1: Global mean sea level change on different time scales and under different scenarios. (a) GMSL change from 1900 to 2150, observed (1900–2018) and projected under the SSP scenarios (2000–2150), relative to a 1995–2014 baseline. Solid lines show median projections. Shaded regions show *likely* ranges for SSP1-2.6 and SSP3-7.0. Dotted and dashed lines show respectively the 83rd and 95th percentile low-confidence projections for SSP5-8.5. Bars at right show *likely* ranges for SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 in 2150. Lightly shaded thick/thin bars show 17th–83rd/5th–95th percentile *low-confidence* ranges in 2150 for SSP1-2.6 and SSP5-8.5, based upon projection methods incorporating structured expert judgement and Marine Ice Cliff Instability. *Low-confidence* range for SSP5-8.5 in 2150 extends to 4.8/5.4 m at the 83rd/95th percentile. (b) GMSL change on 100- (blue), 2,000- (green) and 10,000-year (magenta) time scales as a function of global surface temperature, relative to 1850–1900. For 100-year projections, GMSL is projected for the year 2100, relative to a 1995-2014 baseline, and temperature anomalies are average values over 2081–2100. For longer-term commitments, warming is indexed by peak warming above 1850–1900 reached after cessation of emissions. Shaded regions show paleo-constraints on global surface temperature and GMSL for the Last Interglacial and mid-Pliocene Warm Period. Lightly shaded thick/thin blue bars show 17th–83rd/5th–95th percentile *low-confidence* ranges for SSP1-2.6 and SSP5-8.5 in 2100, plotted at 2°C and 5°C. (c) Timing of exceedance of GMSL thresholds of 0.5, 1.0, 1.5 and 2.0 m, under different SSPs. Lightly shaded thick/thin bars show 1th7–83rd/5th–95th percentile *low-confidence* ranges for SSP1-2.6 and SSP5-8.5.

Box TS.5, Figure 1: Carbon cycle processes and projections. Carbon cycle response to forcings. The figure shows changes in carbon storage in response to elevated CO_2 (a, b) and the response to climate warming (c, d). Maps show spatial patterns of changes in carbon uptake during simulations with 1% per year increase in CO_2 {section 5.4.5.5}, and zonal mean plots show distribution of carbon changes is dominated by the land (green lines) in the tropics and northern hemisphere and ocean (blue lines) in the southern hemisphere. Hatching indicates regions where fewer than 80% of models agree on the sign of response. (e) Future CO_2 projections: projected CO_2 concentrations in the SSP scenarios in response to anthropogenic emissions, results from coupled ESMs for SSP5-8.5 and from the MAGICC7 emulator for other scenarios {section 4.3.1}. (f) Future carbon fluxes:

ACCEPTED VERSION SUBJECT TO FINAL EDITING

projected combined land and ocean fluxes (positive downward) up to 2100 for the SSP scenarios, and extended to 2300 for available scenarios, 5-95% uncertainty plumes shown for SSP1-2.6 and SSP3-7.0 {section 5.4.5.4, 5.4.10}. The numbers near the top show the number of model simulations used. (g) Sink fraction: the fraction of cumulative emissions of CO_2 removed by land and ocean sinks. The sink fraction is smaller under conditions of higher emissions. {5.4.5, 5.5.1; Figure 5.27; Figure 4.31; Figure 5.25; Figure 5.30; Figure 5.31}

Figure TS.12: Land-related changes relative to the 1850-1900 as a function of global warming levels. a) Changes in the frequency (left scale) and intensity (in °C, right scale) of daily hot extremes occurring every 10- and 50-years; b) as a), but for daily heavy precipitation extremes, with intensity change in %; c) Changes in 10-year droughts aggregated over drought-prone regions (CNA, NCA, SCA, NSA, SAM, SWS, SSA, MED, WSAF, ESAF, MDG, SAU, and EAU; for definitions of these regions, see Atlas.2), with drought intensity (right scale) represented by the change of annual mean soil moisture, normalized with respect to interannual variability; d) Changes in Northern Hemisphere spring (March-April-May) snow cover extent relative to 1850-1900; e,f) Relative change (%) in annual mean of total precipitable water (grey line), precipitation (red solid lines), runoff (blue solid lines) and in standard deviation (i.e. variability) of precipitation (red dashed lines) and runoff (blue dashed lines) averaged over (e) tropical and (f) extratropical land as function of global warming levels. CMIP6 models that

reached a 5°C warming level in the 21st century in SSP5-8.5 above the 1850-1900 average have been used. Precipitation and runoff variability are estimated by respective standard deviation after removing linear trends. Error bars show the 17-83% confidence interval for the warmest +5°C global warming level. {Figures 11.6, 11.7, 11.12, 11.15, 11.18, 9.24, 8.16, Atlas.2}

Figure TS.13: **Estimates of the net cumulative energy change (ZJ = 10^{21} Joules) for the period 1971–2018 associated with: (a) observations of changes in the Global Energy Inventory (b) Integrated Radiative Forcing; (c) Integrated Radiative Response.** *The intent is to show assessed changes in energy budget and ERFs.* Black dotted lines indicate the central estimate with *likely* and *very likely* ranges as indicated in the legend. The grey dotted lines indicate the energy change associated with an estimated pre-industrial Earth energy imbalance of 0.2 W m^{-2} (panel a) and an illustration of an assumed pattern effect of –0.5 W m^{-2} °C^{-1} (panel c). Background grey lines indicate equivalent heating rates in W m^{-2} per unit area of Earth's surface. Panels (d) and (e) show the breakdown of components, as indicated in the legend, for the Global Energy Inventory and Integrated Radiative Forcing, respectively. Panel (f) shows the Global Energy Budget assessed for the period 1971–2018, that is, the consistency between the change in the Global Energy Inventory relative to pre-industrial and the implied energy change from Integrated Radiative Forcing plus Integrated Radiative Response under a number of different assumptions, as indicated in the figure legend, including assumptions of correlated and uncorrelated uncertainties in Forcing plus Response. Shading represents the *very likely* range for observed energy change relative to pre-industrial and *likely* range for all other quantities. Forcing and Response timeseries are expressed relative to a baseline period of 1850–1900.

Figure TS.14: Schematic representation of changes in the top-of atmosphere (TOA) radiation budget following a perturbation. *The intent of the figure is to illustrate the concept of adjustments in the climate system following a perturbation in the radiation budget.* The baseline TOA energy budget (a) responds instantaneously to perturbations (b), leading to adjustments in the atmospheric meteorology and composition, and land surface that are independent of changes in surface temperature (c). Surface temperature changes (here using an increase as an example) lead to physical, biogeophysical and biogeochemical feedback processes (d). Long term feedback processes, such as those involving ice sheets, are not shown here. {adapted from Chapter 7 Figure 7.2, FAQ 7.2 Figure 1, and Figure 8.3}

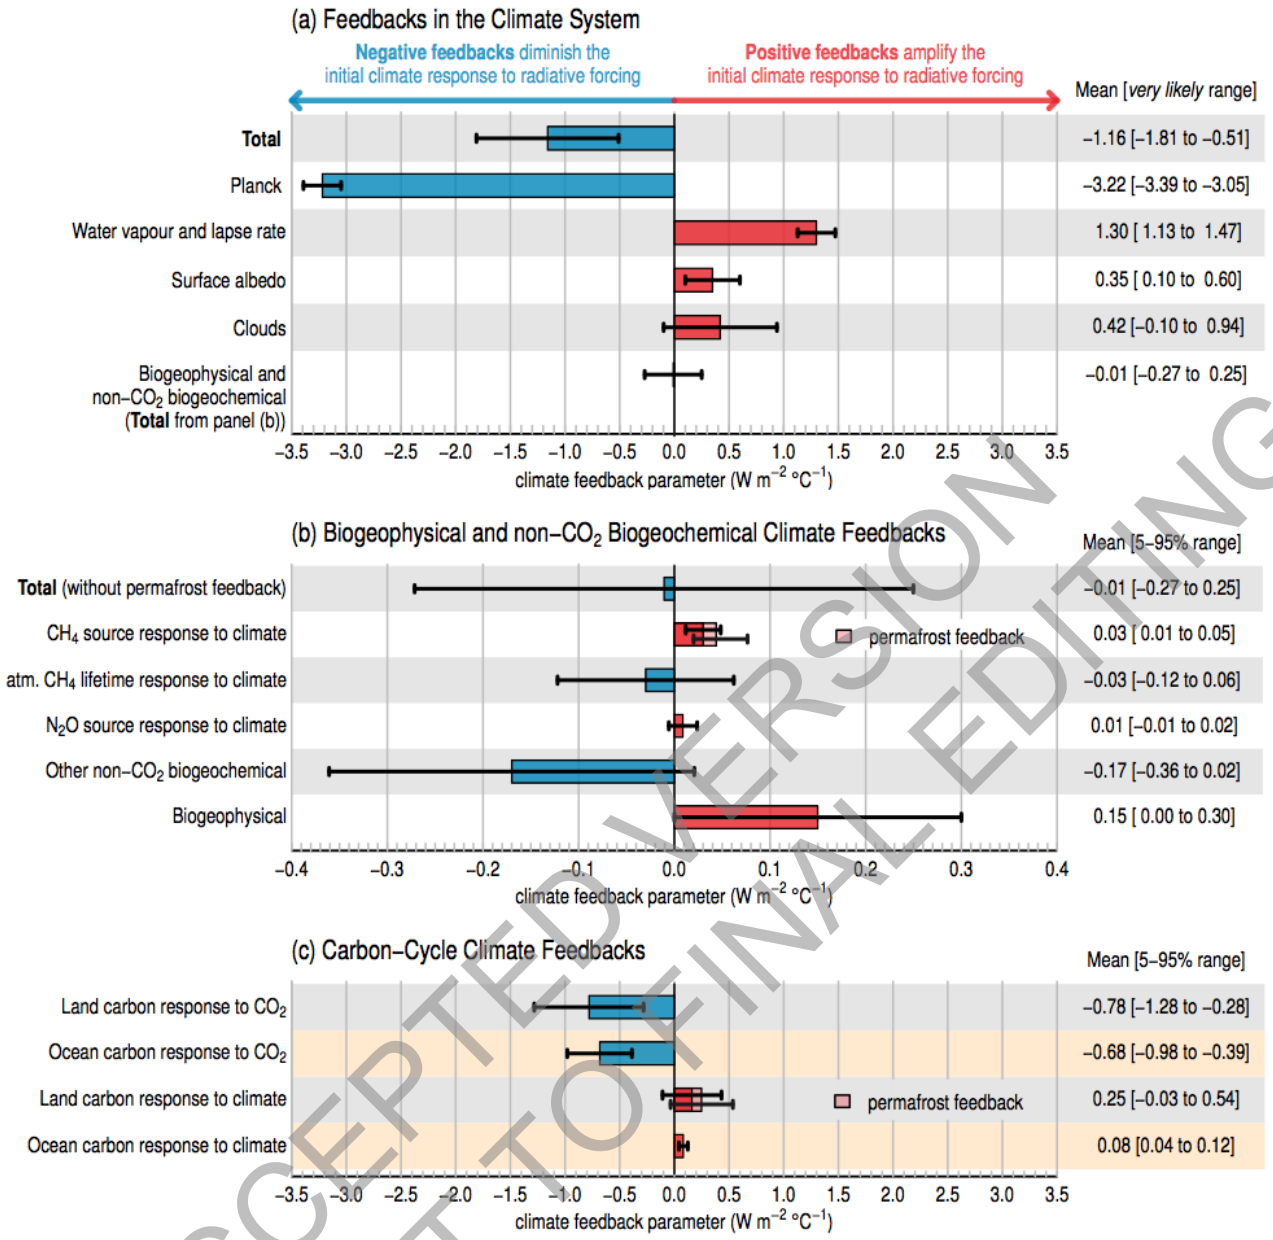
Figure TS.15: **Contribution to ERF and b) global surface temperature change from component emissions between 1750 to 2019 based on CMIP6 models and c) net aerosol effective radiative forcing (ERF) from different lines of evidence.** *The intent of the figure is to show advances since AR5 in the understanding of a) aerosol ERF from different lines of evidence as assessed in Chapter 7, b) emissions-based ERF and c) global surface temperature response for SLCFs as estimated in Chapter 6.* In panel a), ERFs for well-mixed greenhouse gases (WMGHGs) are from the analytical formulae. ERFs for other components are multi-model means based on ESM simulations that quantify the effect of individual components. The derived emission-based ERFs are rescaled to match the concentration-based ERFs in Figure 7.6. Error bars are 5-95% and for the ERF account for uncertainty in radiative efficiencies and multi-model error in the means. In panel b), the global mean temperature response is calculated from the ERF time series using an impulse response function. In panel c), the AR6 assessment is based on energy balance constraints, observational evidence from satellite retrievals, and climate model-based evidence. For each line of evidence the assessed best-estimate contributions from ERF due to ERFari and ERFaci are shown with darker and paler shading, respectively. Estimates from individual CMIP5 and CMIP6 models are depicted by blue and red crosses, respectively. The observational assessment for ERFari is taken from the instantaneous forcing due to aerosol-radiation interactions (IRFari). Uncertainty ranges are given in black bars for the total aerosol ERF and depict *very likely* ranges. {Sections 7.3.3, 6.4.2, Cross-Chapter Box 7.1, Figures 6.12, 7.5 ; Table 7.8}



ACCEPTED VERSION SUBJECT TO FINAL EDITING

The intent is to show a) the progression in ECS including uncertainty and the lines of evidence used for assessment, b) and c) show the lines of assessment used to assess ECS and TCR in AR6.

Figure TS.16: **a) Evolution of equilibrium climate sensitivity (ECS) assessments from the Charney Report through a succession of IPCC Assessment Reports to AR6, and lines of evidence and combined assessment for (b) ECS and (c) transient climate response (TCR) in AR6.** In panel (a), the lines of evidence considered are listed below each assessment. Best estimates are marked by horizontal bars, likely ranges by vertical bars, and very likely ranges by dotted vertical bars. In panel (b) and (c), assessed ranges are taken from Tables 7.13 and 7.14 for ECS and TCR respectively. Note that for the ECS assessment based on both the instrumental record and paleoclimates, limits (i.e., one-sided distributions) are given, which have twice the probability of being outside the maximum/minimum value at a given end, compared to ranges (i.e., two tailed distributions) which are given for the other lines of evidence. For example, the *extremely likely* limit of greater than 95% probability corresponds to one side of the *very likely* (5% to 95%) range. Best estimates are given as either a single number or by a range represented by grey box. CMIP6 ESM values are not directly used as a line of evidence but are presented on the Figure for comparison. {Sections 1.5, 7.5; Tables 7.13, 7.14; Figures 7.18}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure TS.17: An overview of physical and biogeochemical feedbacks in the climate system. *The intent is to summarize assessed estimates of physical, biogeophysical and biogeochemical feedbacks on global temperature based on Chapters 5, 6 and 7.* (a) Synthesis of physical, biogeophysical and non-CO_2 biogeochemical feedbacks that are included in the definition of ECS assessed in this Technical Summary. These feedbacks have been assessed using multiple lines of evidence including observations, models and theory. The net feedback is the sum of the Planck response, water vapour and lapse rate, surface albedo, cloud, and biogeophysical and non-CO_2 biogeochemical feedbacks. Bars denote the mean feedback values and uncertainties represent *very likely* ranges; (b) Estimated values of individual biogeophysical and non-CO_2 biogeochemical feedbacks. The atmospheric methane lifetime and other non-CO_2 biogeochemical feedbacks have been calculated using global Earth System Model simulations from AerChemMIP, while the CH_4 and N_2O source responses to climate have been assessed for the year 2100 using a range of modelling approaches using simplified radiative forcing equations. The estimates represent the mean and 5-95% range. The level of confidence in these estimates is *low* owing to the large model spread. (c) carbon-cycle feedbacks as simulated by models participating in the C4MIP of CMIP6. An independent estimate of the additional positive carbon-cycle climate feedbacks from permafrost thaw, which is not considered in most C4MIP models, is added. The estimates represent the mean and 5-95% range. Note that these

feedbacks act through modifying the atmospheric concentration of CO_2 and thus are not included in the definition of ECS, which assumes a doubling of CO_2, but are included in the definition and assessed range of TCRE. {Sections Box 5.1, 5.4.7, 5.4.8, 6.4.5, 7.4.2, Figure 5.29, Tables 6.9, 7.10}

The intent is to show the proportionality between cumulative CO_2 emissions and global surface air temperature in observations and models (left) as well as the assessed range of TCRE and the right-hand panel shows how information is combined to derive remaining carbon budgets consistent with limiting warming to a specific level.

Figure TS.18: Illustration of (a) relationship between cumulative emissions of CO_2 and global mean surface air temperature increase and (b) the assessment of the remaining carbon budget from its constituting components based on multiple lines of evidence. Carbon budgets consistent with various levels of additional warming are provided in Table 5.8 and should not be read from the illustrations in either panel. In panel (a) thin black line shows historical CO_2 emissions together with the assessed global surface temperature increase from 1850-1900 as assessed in Chapter 2 (Box 2.3). The orange-brown range with its central line shows the estimated human-induced share of historical warming. The vertical orange-brown line shows the assessed range of historical human-induced warming for the 2010–2019 period relative to 1850-1900 (Chapter 3). The grey cone shows the assessed *likely* range for the transient climate response to cumulative emissions of carbon dioxide (TCRE) (Section 5.5.1.4), starting from 2015. Thin coloured lines show CMIP6 simulations for the five scenarios of the WG1 core set (SSP1-1.9, green; SSP1-2.6, blue; SSP2-4.5, yellow; SSP3-7.0, red; SSP5-8.5, maroon), starting from 2015 and until 2100. Diagnosed carbon emissions are complemented with estimated land-use change emissions for each respective scenario. Coloured areas show the Chapter 4 assessed *very likely* range of global surface temperature projections and thick coloured central lines the median estimate, for each respective scenario, relative to the original scenario emissions. For panel (b), the remaining allowable warming is estimated by combining the global warming limit of interest with the assessed historical human induced warming (Section 5.5.2.2.2), the assessed future potential non-CO2 warming contribution (Section 5.5.2.2.3) and the ZEC (Section 5.5.2.2.4). The remaining allowable warming (vertical blue bar) is subsequently combined with the assessed TCRE (Section 5.5.1.4 and 5.5.2.2.1) and contribution of unrepresented Earth system feedbacks (Section 5.5.2.2.5) to provide an assessed estimate of the remaining carbon budget (horizontal blue bar, Table 5.8). Note that contributions in panel (b) are illustrative and are not to scale. For example, the central ZEC estimate was assessed to be zero. {Box 2.3; Sections 5.2.1, 5.2.2; Figure 5.31}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

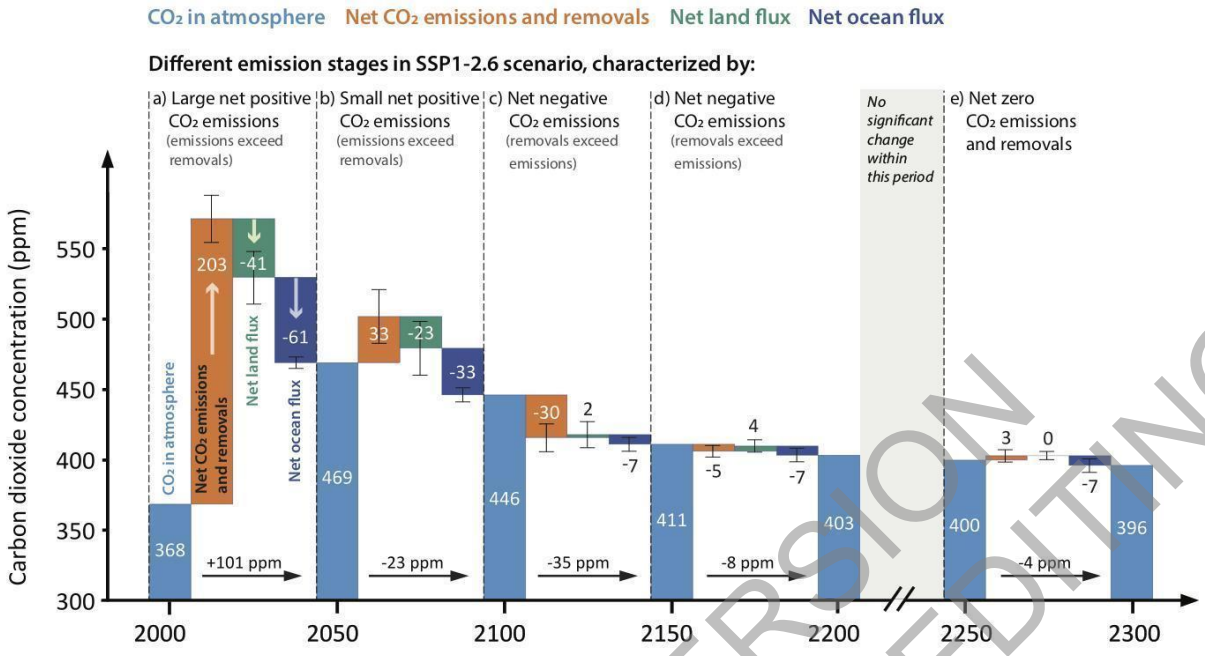

Figure TS.19: **Carbon sink response in a scenario with net CO_2 removal from the atmosphere. .** *The intent of this figure is to show how atmospheric CO_2 evolves under negative emissions and its dependence on the negative emissions technologies. It also shows the evolution of the ocean and land sinks.* Shown are CO_2 flux components from concentration-driven Earth system model simulations during different emission stages of SSP1–2.6 and its long-term extension. (a) Large net positive CO_2 emissions, (b) small net positive CO_2 emissions, (c) – (d) net negative CO_2 emissions, (e) net zero CO_2 emissions. Positive flux components act to raise the atmospheric CO_2 concentration, whereas negative components act to lower the CO_2 concentration. Net CO_2 emissions, land and ocean CO_2 fluxes represent the multi-model mean and standard deviation (error bar) of four ESMs (CanESM5, UKESM1, CESM2-WACCM, IPSL-CM6a-LR) and one EMIC (UVic ESCM). Net CO_2 emissions are calculated from concentration-driven Earth system model simulations as the residual from the rate of increase in atmospheric CO_2 and land and ocean CO_2 fluxes. Fluxes are accumulated over each 50-year period and converted to concentration units (ppm). {5.6.2.1, Figure 5.33}

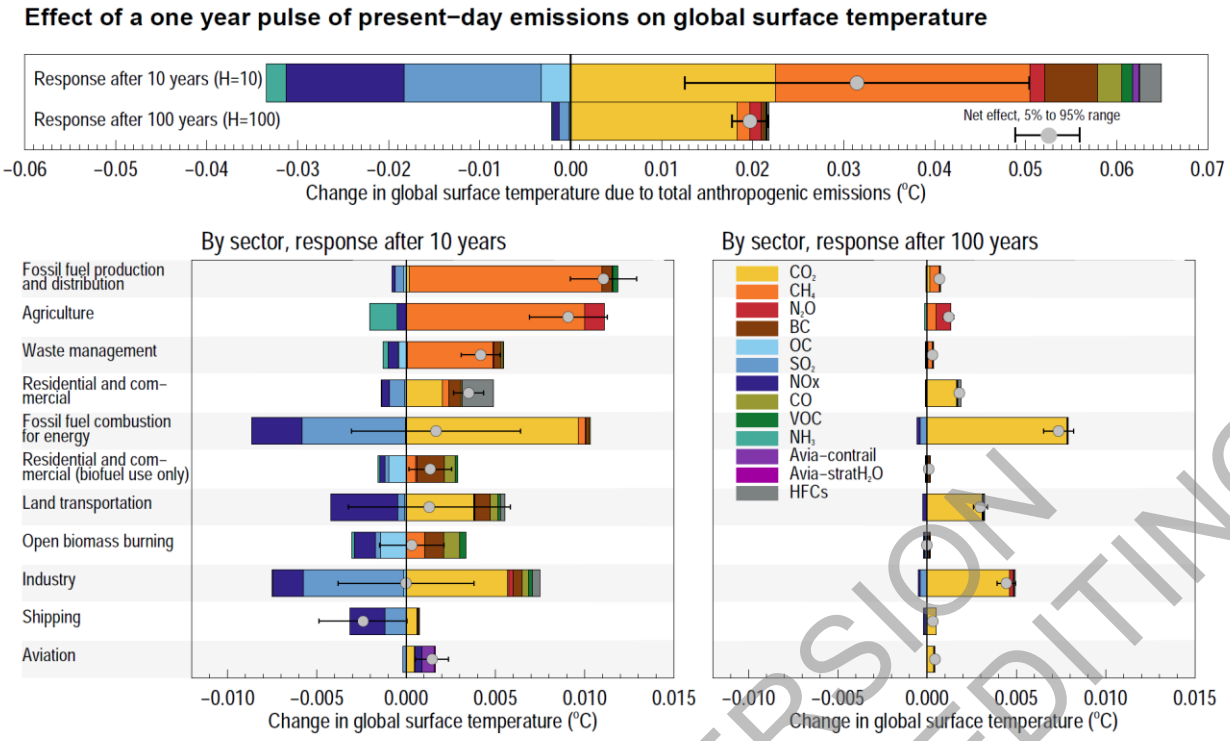
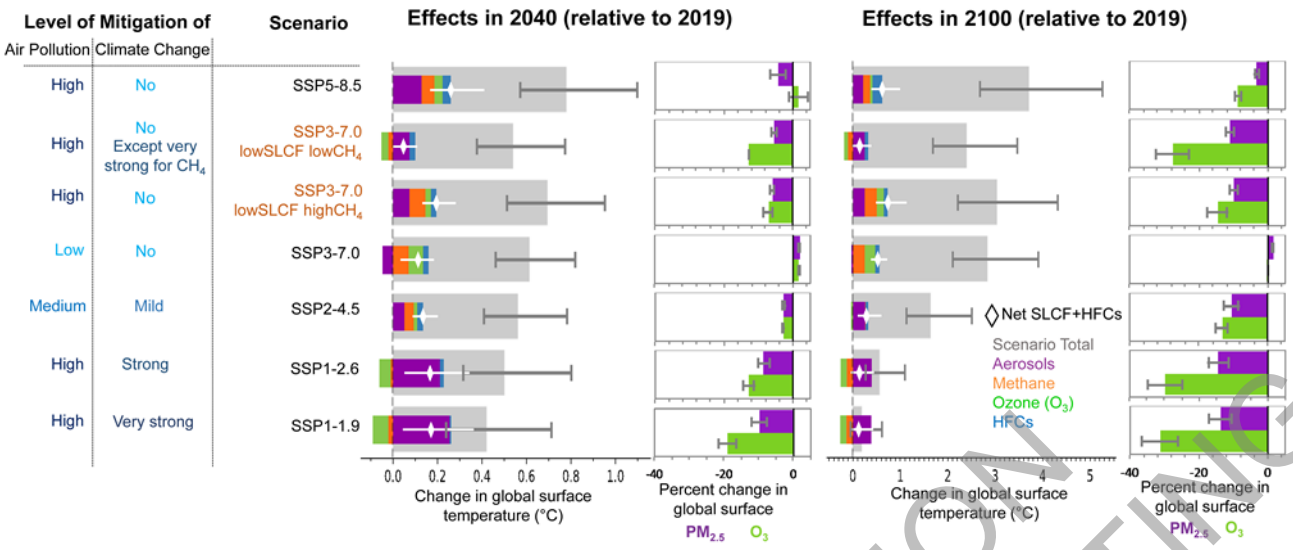
ACCEPTED VERSION SUBJECT TO FINAL EDITING





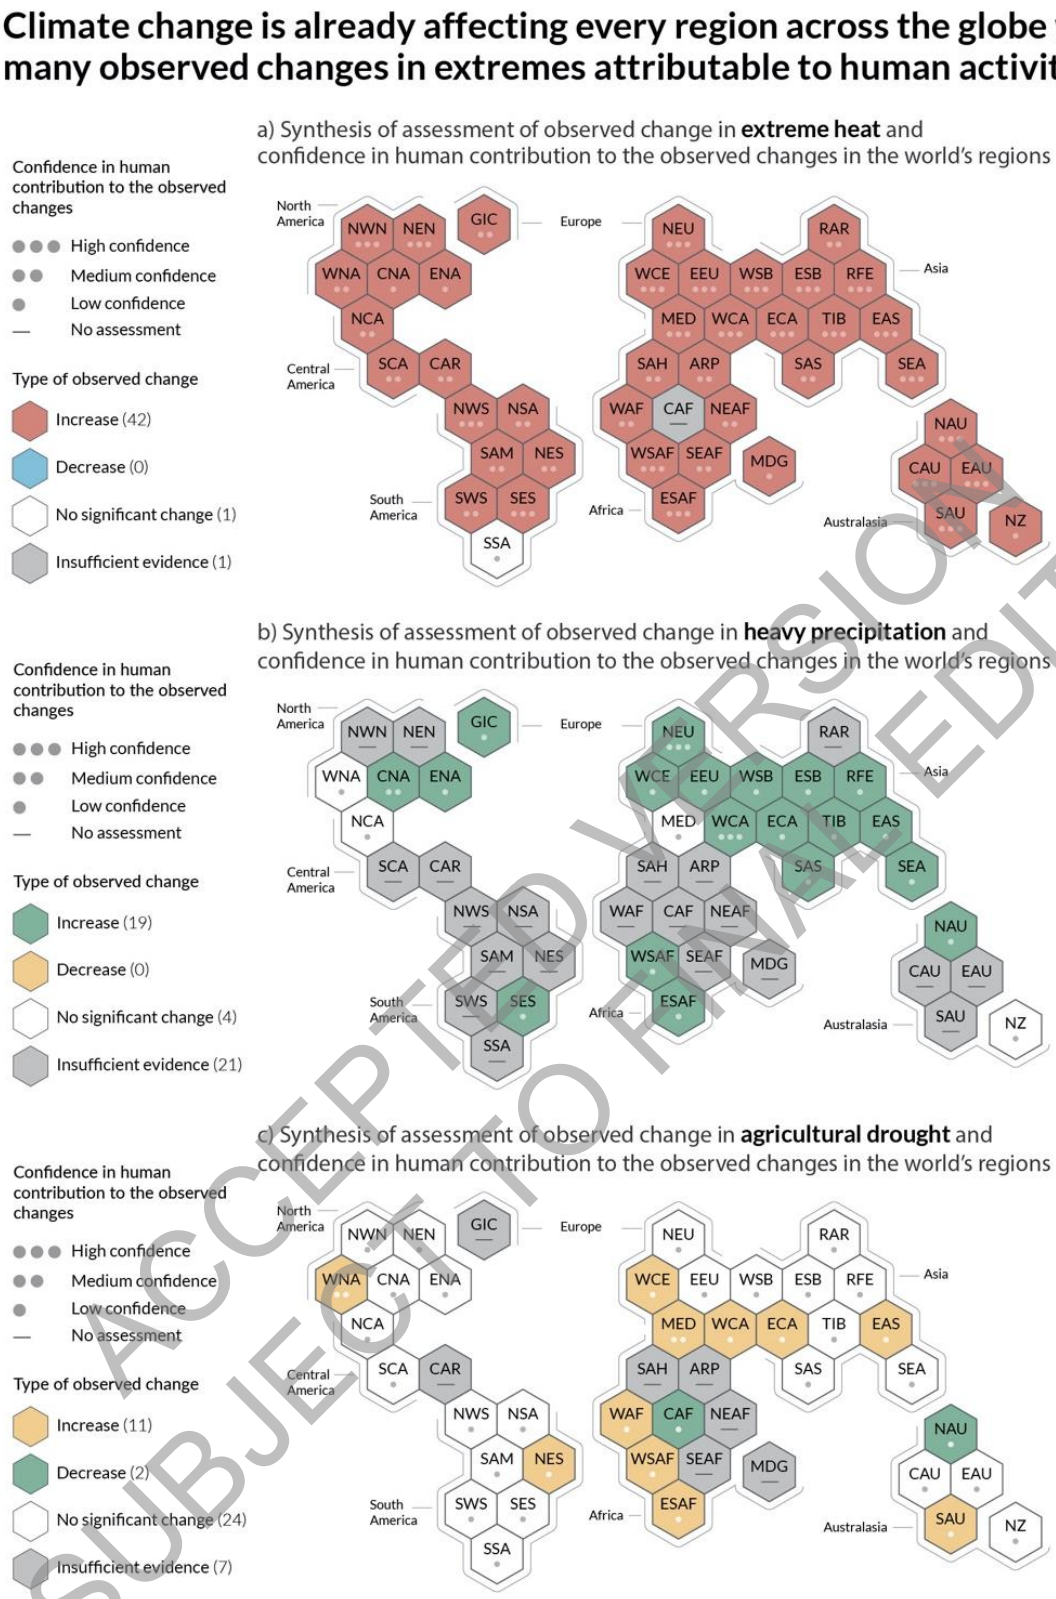


Figure TS.20: **Global surface temperature change 10 and 100 years after a one year pulse of present-day emissions**. *This figure shows the sectoral contribution to present-day climate change by specific climate forcers including CO_2 as well as SLCFs.* The temperature response is broken down by individual species and shown for total anthropogenic emissions (top), and sectoral emissions on 10-year (left) and 100-year time scales (right). Sectors are sorted by (high-to-low) net temperature effect on the 10-year time scale. Error bars in the top panel show the 5-95% range in net temperature effect due to uncertainty in radiative forcing only (calculated using a Monte Carlo approach and best estimate uncertainties from the literature). Emissions for 2014 are from the CMIP6 emissions dataset, except for HFCs and aviation H_2O which rely on other datasets (see Section 6.6.2 for more details). CO_2 emissions are excluded from open biomass burning and residential biofuel use. {6.6.2, Figure 6.16}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Box TS.7, Figure 1: Effects of short-lived climate forcers (SLCFs) on global surface temperature and air pollution across the WG1 core set of Shared Socio-Economic Pathways (SSPs). *The intent of this figure is to show the climate and air quality (surface ozone and $PM_{2.5}$) response to SLCFs in the SSP scenarios for near and long-term.* Effects of net aerosols, tropospheric ozone, hydrofluorocarbons (HFCs) (with lifetimes less than 50 years), and methane are compared with those of total anthropogenic forcing for 2040 and 2100 relative to year 2019. The global surface temperature changes are based on historical and future evolution of Effective Radiative Forcing (ERF) as assessed in chapter 7 of this report. The temperature responses to the ERFs are calculated with a common impulse response function (R_T) for the climate response, consistent with the metric calculations in Chapter 7 (Box 7.1). The R_T has an equilibrium climate sensitivity of 3.0°C for a doubling of atmospheric CO_2 concentration (feedback parameter of -1.31 W m^{-2} $°C^{-1}$). The scenario total (grey bar) includes all anthropogenic forcings (long- and short-lived climate forcers, and land use changes). Uncertainties are 5-95% ranges. The global changes in air pollutant concentrations (ozone and $PM_{2.5}$) are based on multimodel CMIP6 simulations and represent changes in 5-year mean surface continental concentrations for 2040 and 2098 relative to 2019. Uncertainty bars represent inter-model ±1 standard deviation. {6.7.2, 6.7.3, Figure 6.24}

Box TS.10, Figure 1: Synthesis of assessed observed changes and human influence of hot extremes (panel a), heavy precipitation (panel b) and agricultural and ecological drought (panel c) for the IPCC AR6 regions (displayed as hexagons). The colours in each panel represent the four outcomes of the assessment on the observed changes: In Panel a): red – at least *medium confidence* in an observed increase in hot extremes; blue – at least *medium confidence* in an observed decrease in hot extremes; white – no significant change in hot extremes is observed for

the region as a whole; grey – the evidence in this region is insufficient (because of a lack of data and/or literature) to make an assessment for the region as a whole. In panel b): green – at least *medium confidence* in an observed increase in heavy rainfall; yellow - at least *medium confidence* in an observed decrease in heavy rainfall; white – no significant change in heavy rainfall is observed for the region as a whole; grey – the evidence in this region is insufficient (because of a lack of data and/or literature) to make an assessment for the region as a whole. In panel c): yellow – at least *medium confidence* in an observed increase in agricultural and ecological drought; green - at least *medium confidence* in an observed decrease in agricultural and ecological drought; white – no significant change in agricultural and ecological drought is observed for the region as a whole; grey – the evidence in this region is insufficient (because of a lack of data and/or literature) to make an assessment for the region as a whole. Each panel represents in addition the synthesis of assessment of the human influence on the observed changes based on available trend detection and attribution and event attribution scientific publications. The level of confidence is indicated by a number of dots: *high confidence* (three dots), *medium confidence* (two dots), *low confidence* (one dot), and when no assessment is possible, due to insufficient evidence for the specific region (horizontal bar). For hot extremes, the evidence is mostly drawn from changes in metrics based on daily maximum temperatures, regional studies using other metrics (heatwave duration, frequency and intensity) are used in addition {11.9.2}. For heavy precipitation, the evidence is mostly drawn from changes in metrics based on one-day or five-day precipitation amounts using global and regional studies {11.9.3}. Agricultural and ecological droughts are assessed based on observed and projected changes in total column soil moisture, complemented by evidence on changes in surface soil moisture, water-balance (precipitation minus evapotranspiration) and metrics driven by precipitation and atmospheric evaporative demand. {11.9.3} All assessments are made for each AR6 region as a whole and for the timeframe from 1950 to present thus, more local or assessment made on shorter time scales might differ from what is shown in the figure. {11.9, Table TS.5}.

Figure TS.21: **Example of the interplay between drivers of climate variability and change at regional scale to understand past and projected changes.** *The figure intent is to show an illustrative pathway for understanding past, and anticipating future, climate change at regional scale in the presence of uncertainties.* (a) Identification of the climate drivers and their influences on climate phenomena contributing through teleconnection to Southeastern South America summer (DJF) precipitation variability and trends observed over 1950–2014. Drivers (red squares) include MoVs as well as external forcing. Observed precipitation linear trend from GPCC is shown on continents (green-brown colour bar in mm month^{-1} per decade) and the SES AR6 WGI reference region is outlined with the thick black contour. Climate phenomena leading to local impact on SES are schematically presented (blue ovals). (b) Time series of decadal precipitation anomalies for DJF SES simulated from seven large ensembles of historical + RCP8.5 simulations over 1950–2100. Shading corresponds to the 5th–95th range of climate outcomes given from each large ensemble for precipitation (in mm/month) and thick coloured lines stand for their respective ensemble mean. The thick timeseries in white corresponds to the multi-model multi-member ensemble mean with model contribution being weighted according to their ensemble size. GPCC observation is shown in the light black line with squares over 1950–2014 and the 1995–2014 baseline period has been retained for calculation of anomalies in all datasets. (c) Quantification of the respective weight (in percent) between the individual sources of uncertainties (internal in gray, model in magenta and scenario in green) at near-term, mid-term and long-term temporal windows defined in AR6 and highlighted in (b) for SES DJF precipitation. All computations are done with respect to 1995–2014, taken as the reference period and the scenario uncertainty is estimated from CMIP5 using the same set of models as for the large ensembles that have run different RCP scenarios. {Figure 10.12a}

Box TS.13, Figure 1: Global and regional monsoons: past trends and projected changes: *The intent of this figure is to show changes in precipitation over regional monsoon domains in terms of observed past trends and related attribution, and in terms of future projections in one intermediate emission scenario in the near, medium and long terms.* (a) Global (black contour) and regional monsoons (color shaded) domains. The global monsoon (*GM*) is defined as the area with local summer-minus-winter precipitation rate exceeding 2.5 mm day^{-1} (see Annex V). The regional monsoon domains are defined based on published literature and expert judgement (see Annex V), and also accounting for the fact that the climatological summer monsoon rainy season varies across the individual regions. Assessed regional monsoons are South and Southeast Asia (*SAsiaM, Jun-Jul-Aug-Sep*), East Asia (*EAsiaM, Jun-Jul-Aug*), West Africa (*WAfriM, Jun-Jul-Aug-Sep*), North America (*NAmerM, Jul-Aug-Sep*), South America (*SAmerM, Dec-Jan-Feb*), Australia and Maritime Continent Monsoon (*AusMCM, Dec-Jan-Feb*). Equatorial South America (*EqSAmer*) and South Africa (*SAfri*) regions are also shown, as they receive unimodal summer seasonal rainfall although their qualification as monsoons is subject to discussion. (b) Global and regional monsoons precipitation trends based on DAMIP CMIP6 simulations with both natural and anthropogenic (ALL), GHG only (GHG), aerosols only (AER) and natural only (NAT) radiative forcing. Weighted ensemble means are based on nine CMIP6 models contributing to the MIP (with at least 3 members). Observed trends computed from CRU GPCP, and APHRO (only for *SAsiaM* and *EAsiaM*) datasets are shown as well. (c) Percentage change in projected seasonal mean precipitation over global and regional monsoons domain in the near-term (2021–2040),

Figure TS.22: (Panel a): shows the geographical location of regions belonging to one of five groups characterized by a specific combination of changing climatic impact-drivers (CIDs). The five groups are represented by the five different colours, and the CID combinations associated with each group are represented in the corresponding 'fingerprint' and text below the map. Each fingerprint comprises a set of CIDs projected to change with high confidence in every region in the group, and a second set of CIDs, one or more of which are projected to change in each region with high or medium confidence. The CID combinations follow a progression from those becoming hotter and drier (group 1) to those becoming hotter and wetter (group 5). In between (groups 2–-4), the CIDs that change include some becoming drier and some wetter and always include a set of CIDs which are getting hotter. Tropical cyclones and severe wind CID changes are represented on the map with black dots in the regions affected. Regions affected by coastal CID changes are described by text on the map. The five groups are chosen to provide a reasonable level of detail for each region-specific detail whilst not overwhelming the map with a full summary all aspects of the assessment, which is available in Table TS.5. [Placeholder: This summary is also represented visually in the Interactive Atlas.] The CID changes summarized in the figure represent high and medium confidence changes projected if a level of 2°C of global warming is attained around 2050. The bar chart in panel b) shows the numbers of regions where each CID is increasing or decreasing with medium or high confidence for all land regions reported in the map of panel a) and for the ocean regions. The regions coloured in the map comprise the WG I AR6 reference regions, which include inhabited land areas and an additional non-continuous Pacific Islands region labelled PAC. Definitions of the acronyms of the other regions are provided in Atlas.1 and the Interactive Atlas. {Table TS.5, Figure TS.24}

Figure TS.25: **Distribution of projected changes in selected climatic impact-driver indices for selected regions for CMIP6, CMIP5 and CORDEX model ensembles.** Different indices are shown for different region: for east Europe and north Asia the mean number of days per year with maximum temperature exceeding 35°C, for Central America and the Caribbean, and the Arabian peninsula, western, southern and easten Asia the mean number of days per year with the NOAA Heat Index exceeding 41°C, for Australasia, East Asia and Russia far East the average shoreline position change, for South America, Europe and Africa the mean change in 1-in-100-years river discharge per unit catchment area (m3 s–1 km–2), and for North America the median change in the number of days with snow water equivalent (SWE) over 100 mm. For each box plot the changes or the climatological values are reported respect to, or compared to, the recent past (1995–2014) period for 1.5 ºC, 2ºC and 4ºC global warming levels and for mid-century (2041–2060) or end-century (2081–2100) periods for the CMIP5 and CORDEX RCP8.5 and RCP2.6 and CMIP6 SSP5-8.5 and SSP1-2.6 scenarios ensembles {Figure 12.5, Figure 12.6, Figure 12.9, Figure 12.SM.1, Figure 12.SM.2, Figure 12.SM.6}.

Executive Summary

Working Group I (WGI) of the Intergovernmental Panel on Climate Change (IPCC) assesses the current evidence on the physical science of climate change, evaluating knowledge gained from observations, reanalyses, paleoclimate archives and climate model simulations, as well as physical, chemical and biological climate processes. This chapter sets the scene for the WGI assessment, placing it in the context of ongoing global and regional changes, international policy responses, the history of climate science and the evolution from previous IPCC assessments, including the Special Reports prepared as part of this Assessment Cycle. Key concepts and methods, relevant recent developments, and the modelling and scenario framework used in this assessment are presented.

Framing and Context of the WGI Report

The WGI contribution to the IPCC Sixth Assessment Report (AR6) assesses new scientific evidence relevant for a world whose climate system is rapidly changing, overwhelmingly due to human influence. The five IPCC assessment cycles since 1990 have comprehensively and consistently laid out the rapidly accumulating evidence of a changing climate system, with the Fourth Assessment Report (AR4, 2007) being the first to conclude that warming of the climate system is unequivocal. Sustained changes have been documented in all major elements of the climate system, including the atmosphere, land, cryosphere, biosphere and ocean. Multiple lines of evidence indicate the unprecedented nature of recent large-scale climatic changes in context of all human history, and that they represent a millennial-scale commitment for the slow-responding elements of the climate system, resulting in continued worldwide loss of ice, increase in ocean heat content, sea level rise and deep ocean acidification. {1.2.1, 1.3, Box 1.2, Appendix 1.A}

Since the IPCC Fifth Assessment Report (AR5), the international policy context of IPCC reports has changed. The UN Framework Convention on Climate Change (UNFCCC, 1992) has the overarching objective of preventing 'dangerous anthropogenic interference with the climate system'. Responding to that objective, the Paris Agreement (2015) established the long-term goals of 'holding the increase in global average temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5°C above pre-industrial levels' and of achieving 'a balance between anthropogenic emissions by sources and removals by sinks of greenhouse gases in the second half of this century'. Parties to the Agreement have submitted Nationally Determined Contributions (NDCs) indicating their planned mitigation and adaptation strategies. However, the NDCs submitted as of 2020 are insufficient to reduce greenhouse gas emission enough to be consistent with trajectories limiting global warming to well below 2°C above pre-industrial levels (*high confidence*). {1.1, 1.2}

This report provides information of potential relevance to the 2023 global stocktake. The 5-yearly stocktakes called for in the Paris Agreement will evaluate alignment among the Agreement's long-term goals, its means of implementation and support, and evolving global efforts in climate change mitigation (efforts to limit climate change) and adaptation (efforts to adapt to changes that cannot be avoided). In this context, WGI assesses, among other topics, remaining cumulative carbon emission budgets for a range of global warming levels, effects of long-lived and short-lived climate forcers, projected changes in sea level and extreme events, and attribution to anthropogenic climate change. {Cross-Chapter Box 1.1}

Understanding of the fundamental features of the climate system is robust and well established. Scientists in the 19th-century identified the major natural factors influencing the climate system. They also hypothesized the potential for anthropogenic climate change due to carbon dioxide (CO_2) emitted by fossil fuel combustion. The principal natural drivers of climate change, including changes in incoming solar radiation, volcanic activity, orbital cycles, and changes in global biogeochemical cycles, have been studied systematically since the early 20th century. Other major anthropogenic drivers, such as atmospheric aerosols (fine solid particles or liquid droplets), land-use change and non-CO_2 greenhouse gases, were identified by the 1970s. Since systematic scientific assessments began in the 1970s, the influence of human activity on the warming of the climate system has evolved from theory to established fact. Past projections of global surface temperature and the pattern of warming are broadly consistent with subsequent observations (*limited evidence, high agreement*), especially when accounting for the difference in radiative forcing scenarios used

ACCEPTED VERSION SUBJECT TO FINAL EDITS

for making projections and the radiative forcings that actually occurred. {1.3.1 - 1.3.6}

Global surface temperatures increased by about 0.1°C (*likely* range –0.1°C to +0.3°C, *medium confidence*) between the period around 1750 and the 1850–1900 period, with anthropogenic factors responsible for a warming of 0.0°C–0.2°C (*likely* range, *medium confidence*). This assessed change in temperature before 1850–1900 is not included in the AR6 assessment of global warming to date, to ensure consistency with previous IPCC assessment reports, and because of the lower confidence in the estimate. There was *likely* a net anthropogenic forcing of 0.0–0.3 Wm^{-2} in 1850–1900 relative to 1750 (*medium confidence*), with radiative forcing from increases in atmospheric greenhouse gas concentrations being partially offset by anthropogenic aerosol emissions and land-use change. Net radiative forcing from solar and volcanic activity is estimated to be smaller than ±0.1 Wm^{-2} for the same period. {Cross Chapter Box 1.2, 1.4.1, Cross Chapter Box 2.3}

Natural climate variability can temporarily obscure or intensify anthropogenic climate change on decadal time scales, especially in regions with large internal interannual-to-decadal variability. At the current level of global warming, an observed signal of temperature change relative to the 1850–1900 baseline has emerged above the levels of background variability over virtually all land regions (*high confidence*). Both the rate of long-term change and the amplitude of interannual (year-to-year) variability differ from global to regional to local scales, between regions and across climate variables, thus influencing when changes become apparent. Tropical regions have experienced less warming than most others, but also exhibit smaller interannual variations in temperature. Accordingly, the signal of change is more apparent in tropical regions than in regions with greater warming but larger interannual variations (*high confidence*). {1.4.2, FAQ1.2}

The AR6 has adopted a unified framework of climate risk, supported by an increased focus in WGI on low-likelihood, high-impact events. Systematic risk framing is intended to aid the formulation of effective responses to the challenges posed by current and future climatic changes and to better inform risk assessment and decision-making. AR6 also makes use of the 'storylines' approach, which contributes to building a robust and comprehensive picture of climate information, allows a more flexible consideration and communication of risk, and can explicitly address low-likelihood, high-impact events. {1.1.2, 1.4.4, Cross-Chapter Box 1.3}

The construction of climate change information and communication of scientific understanding are influenced by the values of the producers, the users and their broader audiences. Scientific knowledge interacts with pre-existing conceptions of weather and climate, including values and beliefs stemming from ethnic or national identity, traditions, religion or lived relationships to land and sea (*high confidence*). Science has values of its own, including objectivity, openness and evidence-based thinking. Social values may guide certain choices made during the construction, assessment and communication of information (*high confidence*). {1.2.3, Box 1.1}

Data, Tools and Methods Used across the WGI Report

Capabilities for observing the physical climate system have continued to improve and expand overall, but some reductions in observational capacity are also evident (*high confidence*). Improvements are particularly evident in ocean observing networks and remote-sensing systems, and in paleoclimate reconstructions from proxy archives. However, some climate-relevant observations have been interrupted by the discontinuation of surface stations and radiosonde launches, and delays in the digitisation of records. Further reductions are expected to result from the COVID-19 pandemic. In addition, paleoclimate archives such as mid-latitude and tropical glaciers as well as modern natural archives used for calibration (e.g., corals and trees) are rapidly disappearing owing to a host of pressures, including increasing temperatures (*high confidence*). {1.5.1}

Reanalyses have improved since AR5 and are increasingly used as a line of evidence in assessments of the state and evolution of the climate system (*high confidence*). Reanalyses, where atmosphere or ocean forecast models are constrained by historical observational data to create a climate record of the past, provide

ACCEPTED VERSION SUBJECT TO FINAL EDITS

consistency across multiple physical quantities and information about variables and locations that are not directly observed. Since AR5, new reanalyses have been developed with various combinations of increased resolution, extended records, more consistent data assimilation, estimation of uncertainty arising from the range of initial conditions, and an improved representation of the ocean. While noting their remaining limitations, the WGI report uses the most recent generation of reanalysis products alongside more standard observation-based datasets. {1.5.2, Annex 1}

Since AR5, new techniques have provided greater confidence in attributing changes in climate extremes to climate change. Attribution is the process of evaluating the relative contributions of multiple causal factors to an observed change or event. This includes the attribution of the causal factors of changes in physical or biogeochemical weather or climate variables (e.g., temperature or atmospheric CO_2) as done in WGI, or of the impacts of these changes on natural and human systems (e.g., infrastructure damage or agricultural productivity), as done in WGII. Attributed causes include human activities (such as emissions of greenhouse gases and aerosols, or land-use change), and changes in other aspects of the climate, or natural or human systems. {Cross-WG Box 1.1}

The latest generation of complex climate models has an improved representation of physical processes, and a wider range of Earth system models now represent biogeochemical cycles. Since the AR5, higher-resolution models that better capture smaller-scale processes and extreme events have become available. Key model intercomparisons supporting this assessment include the Coupled Model Intercomparison Project Phase 6 (CMIP6) and the Coordinated Regional Climate Downscaling Experiment (CORDEX), for global and regional models respectively. Results using CMIP Phase 5 (CMIP5) simulations are also assessed. Since the AR5, large ensemble simulations, where individual models perform multiple simulations with the same climate forcings, are increasingly used to inform understanding of the relative roles of internal variability and forced change in the climate system, especially on regional scales. The broader availability of ensemble model simulations has contributed to better estimations of uncertainty in projections of future change (*high confidence*). A broad set of simplified climate models is assessed and used as emulators to transfer climate information across research communities, such as for evaluating impacts or mitigation pathways consistent with certain levels of future warming. {1.4.2, 1.5.3, 1.5.4, Cross-chapter Box 7.1}

Assessments of future climate change are integrated within and across the three IPCC Working Groups through the use of three core components: scenarios, global warming levels, and the relationship between cumulative carbon emissions and global warming. Scenarios have a long history in the IPCC as a method for systematically examining possible futures. A new set of scenarios, derived from the Shared Socio-economic Pathways (SSPs), is used to synthesize knowledge across the physical sciences, impact, and adaptation and mitigation research. The core set of SSP scenarios used in the WGI report, SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5, cover a broad range of emission pathways, including new low-emissions pathways. The feasibility or likelihood of individual scenarios is not part of this assessment, which focuses on the climate response to possible, prescribed emission futures. Levels of global surface temperature change (global warming levels), which are closely related to a range of hazards and regional climate impacts, also serve as reference points within and across IPCC Working Groups. Cumulative carbon emissions, which have a nearly linear relationship to increases in global surface temperature, are also used. {1.6.1-1.6.4, Cross-Chapter Box 1.5, Cross-Chapter Box 11.1}

ACCEPTED VERSION SUBJECT TO FINAL EDITS

1.1 Report and chapter overview

The role of the Intergovernmental Panel on Climate Change (IPCC) is to critically assess the scientific, technical, and socio-economic information relevant to understanding the physical science and impacts of human-induced climate change and natural variations, including the risks, opportunities and options for adaptation and mitigation. This task is performed through a comprehensive assessment of the scientific literature. The robustness of IPCC assessments stems from the systematic consideration and combination of multiple lines of independent evidence. In addition, IPCC reports undergo one of the most comprehensive, open, and transparent review and revision processes ever employed for science assessments.

Starting with the First Assessment Report (FAR; IPCC, 1990) the IPCC assessments have been structured into three working groups. Working Group I (WGI) assesses the physical science basis of climate change, Working Group II (WGII) assesses associated impacts, vulnerability and adaptation options, and Working Group III (WGIII) assesses mitigation response options. Each report builds on the earlier comprehensive assessments by incorporating new research and updating previous findings. The volume of knowledge assessed and the cross-linkages between the three working groups have substantially increased over time.

As part of its sixth assessment cycle, from 2015 to 2022, the IPCC is producing three Working Group Reports, three targeted Special Reports, a Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories, and a Synthesis Report. The AR6 Special Reports covered the topics of 'Global Warming of 1.5°C' (SR1.5; IPCC, 2018), 'Climate Change and Land' (SRCCL; IPCC, 2019a) and 'The Ocean and Cryosphere in a Changing Climate' (SROCC; IPCC, 2019b). The SR1.5 and SRCCL are the first IPCC reports jointly produced by all three Working Groups. This evolution towards a more integrated assessment reflects a broader understanding of the interconnectedness of the multiple dimensions of climate change.

1.1.1 The AR6 WGI Report

The Sixth Assessment Report (AR6) of the IPCC marks more than 30 years of global collaboration to describe and understand, through expert assessments, one of the defining challenges of the 21st century: human-induced climate change. Since the inception of the IPCC in 1988, our understanding of the physical science basis of climate change has advanced markedly. The amount and quality of instrumental observations and information from paleoclimate archives have substantially increased. Understanding of individual physical, chemical and biological processes has improved. Climate model capabilities have been enhanced, through the more realistic treatment of interactions among the components of the climate system, and improved representation of the physical processes, in line with the increased computational capacities of the world's supercomputers.

This report assesses both observed changes, and the components of these changes that are attributable to anthropogenic influence (or human-induced), distinguishing between anthropogenic and naturally forced changes (see Section 1.2.1.1, Section 1.4.1, Cross Working Group Box: Attribution, and Chapter 3). The core assessment conclusions from previous IPCC reports are confirmed or strengthened in this report, indicating the robustness of our understanding of the primary causes and consequences of anthropogenic climate change.

The WGI contribution to AR6 is focused on physical and biogeochemical climate science information, with particular emphasis on regional climate changes. These are relevant for mitigation, adaptation and risk assessment in the context of complex and evolving policy settings, including the Paris Agreement, the Global Stocktake, the Sendai Framework and the Sustainable Development Goals (SDGs) Framework.

The core of this report consists of twelve chapters plus the Atlas (Figure 1.1), which can together be grouped into three categories (excluding this framing chapter):

Large-Scale Information (Chapters 2, 3 and 4). These chapters assess climate information from global to continental or ocean-basin scales. Chapter 2 presents an assessment of the changing state of the climate

ACCEPTED VERSION SUBJECT TO FINAL EDITS

system, including the atmosphere, biosphere, ocean and cryosphere. Chapter 3 continues with an assessment of the human influence on this changing climate, covering the attribution of observed changes, and introducing the fitness-for-purpose approach for the evaluation of climate models used to conduct the attribution studies. Finally, Chapter 4 assesses climate change projections, from the near to the long term, including climate change beyond 2100, as well as the potential for abrupt and 'low-likelihood, high-impact' changes.

Process Understanding (Chapters 5, 6, 7, 8 and 9). These five chapters provide end-to-end assessments of fundamental Earth system processes and components: the carbon budget and biogeochemical cycles (Chapter 5), short-lived climate forcers and their links to air quality (Chapter 6), the Earth's energy budget and climate sensitivity (Chapter 7), the water cycle (Chapter 8), and the ocean, cryosphere and sea-level changes (Chapter 9). All these chapters provide assessments of observed changes, including relevant paleoclimatic information and understanding of processes and mechanisms as well as projections and model evaluation.

Regional Information (Chapters 10, 11, 12 and Atlas). New knowledge on climate change at regional scales is reflected in this report with four chapters covering regional information. Chapter 10 provides a framework for assessment of regional climate information, including methods, physical processes, an assessment of observed changes at regional scales, and the performance of regional models. Chapter 11 addresses extreme weather and climate events, including temperature, precipitation, flooding, droughts and compound events. Chapter 12 provides a comprehensive, region-specific assessment of changing climatic conditions that may be hazardous or favourable (hence influencing climate risk) for various sectors to be assessed in WGII. Lastly, the Atlas assesses and synthesizes regional climate information from the whole report, focussing on the assessments of mean changes in different regions and on model assessments for the regions. It also introduces the online Interactive Atlas, a novel compendium of global and regional climate change observations and projections. It includes a visualization tool combining various warming levels and scenarios on multiple scales of space and time.

Embedded in the chapters are **Cross-Chapter Boxes** that highlight cross-cutting issues. Each chapter also includes an **Executive Summary (ES),** and several **Frequently Asked Questions (FAQs)**. To enhance traceability and reproducibility of report figures and tables, detailed information on the input data used to create them, as well as links to archived code, are provided in the **Input Data Tables** in chapter Supplementary Material. Additional metadata on the model input datasets is provided via the report website.

The AR6 WGI report includes a **Summary for Policy Makers (SPM)** and a **Technical Summary (TS)**. The integration among the three IPCC Working Groups is strengthened by the implementation of the **Cross-Working-Group Glossary**.

[START FIGURE 1.1 HERE]

Figure 1.1: The structure of the AR6 WGI Report. Shown are the three pillars of the AR6 WGI, its relation to the WGII and WGIII contributions, and the cross-working-group AR6 Synthesis Report (SYR).

[END FIGURE 1.1 HERE]

1.1.2 Rationale for the new AR6 WGI structure and its relation to the previous AR5 WGI Report

The AR6 WGI report, as a result of its scoping process, is structured around topics such as large-scale information, process understanding and regional information (Figure 1.1). This represents a rearrangement relative to the structure of the WGI contribution to the IPCC Fifth Assessment Report (AR5; IPCC, 2013a), as summarized in Figure 1.2. The AR6 approach aims at a greater visibility of key knowledge developments potentially relevant for policymakers, including climate change mitigation, regional adaptation planning based on a risk management framework, and the Global Stocktake.

Figure 1.2: Main relations between AR5 WGI and AR6 WGI chapters. The left column shows the AR5 WGI chapter categories. The central column lists the AR5 WGI chapters, with the colour code indicating their relation to the AR6 WGI structure shown in Figure 1.1: Large-Scale Information (red), Process Understanding (gold), Regional Information (light blue), and Whole-Report Information (dark blue). AR5 WGI chapters depicted in white have their topics distributed over multiple AR6 WGI chapters and categories. The right column explains where to find related information in the AR6 WGI report.

[END FIGURE 1.2 HERE]

Two key subjects presented separately in AR5, paleoclimate and model evaluation, are now distributed among multiple AR6 WGI chapters. Various other cross-cutting themes are also distributed throughout this report. A summary of these themes and their integration across chapters is described in Table 1.1.

[START TABLE 1.1 HERE]

1.1.3 Integration of AR6 WGI assessments with other Working Groups

Integration of assessments across the chapters of the WGI Report, and with WGII and WGIII, occurs in a number of ways, including work on a common Glossary, risk framework (see Cross-Chapter Box 1.3), scenarios and projections of future large-scale changes, and the presentation of results at various global warming levels (see Section 1.6).

Chapters 8 through 12, and the Atlas, cover topics also assessed by WGII in several areas, including regional climate information and climate-related risks. This approach produces a more integrated assessment of impacts of climate change across Working Groups. In particular, Chapter 10 discusses the generation of regional climate information for users, the co-design of research with users, and the translation of information into the user context (in particular directed towards WGII). Chapter 12 provides a direct bridge between physical climate information (climatic impact-drivers) and sectoral impacts and risk, following the chapter organization of the WGII assessment. Notably, Cross-Chapter Box 12.1 draws a connection to representative key risks and Reasons for Concern (RFC).

The science assessed in Chapters 2 to 7, such as the carbon budget, short-lived climate forcers and emission metrics, are topics in common with WGIII, and relevant for the mitigation of climate change. This includes a consistent presentation of the concepts of carbon budget and net zero emission targets within chapters, in order to support integration in the Synthesis Report. Emission-driven emulators (simple climate models), summarised in Cross-Chapter Box 7.1 in Chapter 7 are used to approximate large-scale climate responses of complex Earth System Models (ESMs) and have been used as tools to explore the expected GSAT response to multiple scenarios consistent with those assessed in WGI for the classification of scenarios in WGIII. Chapter 6 provides information about the impact of climate change on global air pollution, relevant for WGII, including Cross-Chapter Box 6.1 on the implications of the recent coronavirus pandemic (COVID-19) for climate and air quality. Cross-Chapter Box 2.3 in Chapter 2 presents an integrated cross-WG discussion of global temperature definitions, with implications for many aspects of climate change science.

In addition, Chapter 1 sets out a shared terminology on cross-cutting topics, including climate risk, attribution and storylines, as well as an introduction to emission scenarios, global warming levels and cumulative carbon emissions as an overarching topic for integration across all three Working Groups.

All these integration efforts are aimed at enhancing the bridges and ‘handshakes’ among Working Groups, enabling the final cross-working group exercise of producing the integrated Synthesis Report.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

1.1.4 Chapter preview

The main purposes of this chapter are: (1) to set the scene for the WGI assessment and to place it in the context of ongoing global changes, international policy processes, the history of climate science and the evolution from previous IPCC assessments, including the Special Reports prepared as part of the sixth assessment cycle; (2) to describe key concepts and methods, relevant developments since AR5, and the modelling framework used in this assessment; and (3) together with the other chapters of this report, to provide context and support for the WGII and WGIII contributions to AR6, particularly on climate information to support mitigation, adaptation and risk management.

The chapter comprises seven sections (Figure 1.3). Section 1.2 describes the present state of Earth's climate, in the context of reconstructed and observed long-term changes and variations caused by natural and anthropogenic factors. It also provides context for the present assessment by describing recent changes in international climate change governance and fundamental scientific values. The evolution of knowledge about climate change and the development of earlier IPCC assessments are presented in Section 1.3. Approaches, methods, and key concepts of this assessment are introduced in Section 1.4. New developments in observing networks, reanalyses, modelling capabilities and techniques since the AR5 are discussed in Section 1.5. The three main 'dimensions of integration' across Working Groups in the AR6, i.e. emission scenarios, global warming levels and cumulative carbon emissions, are described in Section 1.6. The Chapter closes with a discussion of opportunities and gaps in knowledge integration in Section 1.7.

[START FIGURE 1.3 HERE]

Figure 1.3: A roadmap to the contents of Chapter 1.

[END FIGURE 1.3 HERE]

1.2 Where we are now

The IPCC sixth assessment cycle occurs in the context of increasingly apparent climatic changes observed across the physical climate system. Many of these changes can be attributed to anthropogenic influences, with impacts on natural and human systems. AR6 also occurs in the context of efforts in international climate governance such as the Paris Agreement, which sets a long-term goal to hold the increase in global average temperature to 'well below 2°C above pre-industrial levels, and to pursue efforts to limit the temperature increase to 1.5°C above pre-industrial levels, recognizing that this would significantly reduce the risks and impacts of climate change'. This section summarises key elements of the broader context surrounding the assessments made in the present report.

1.2.1 The changing state of the physical climate system

The WGI contribution to the AR5 (AR5 WGI; IPCC, 2013a) assessed that 'warming of the climate system is unequivocal', and that since the 1950s, many of the observed changes are unprecedented over decades to millennia. Changes are evident in all components of the climate system: the atmosphere and the ocean have warmed, amounts of snow and ice have diminished, sea level has risen, the ocean has acidified and its oxygen content has declined, and atmospheric concentrations of greenhouse gases have increased (IPCC, 2013b). This Report documents that, since the AR5, changes to the state of the physical and biogeochemical climate system have continued, and these are assessed in full in later chapters. Here, we summarize changes to a set of key large-scale climate indicators over the modern era (1850 to present). We also discuss the changes in relation to the longer-term evolution of the climate. These ongoing changes throughout the climate system form a key part of the context of the present report.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

1.2.1.1 Recent changes in multiple climate indicators

The physical climate system comprises all processes that combine to form weather and climate. The early chapters of this report broadly organize their assessments according to overarching realms: the atmosphere, the biosphere, the cryosphere (surface areas covered by frozen water, such as glaciers and ice sheets), and the ocean. Elsewhere in the report, and in previous IPCC assessments, the land is also used as an integrating realm that includes parts of the biosphere and the cryosphere. These overarching realms have been studied and measured in increasing detail by scientists, institutions, and the general public since the 18th century, over the era of instrumental observation (see Section 1.3). Today, observations include those taken by numerous land surface stations, ocean surface measurements from ships and buoys, underwater instrumentation, satellite and surface-based remote sensing, and in situ atmospheric measurements from airplanes and balloons. These instrumental observations are combined with paleoclimate reconstructions and historical documentations to produce a highly detailed picture of the past and present state of the whole climate system, and to allow assessments about rates of change across the different realms (see Chapter 2 and Section 1.5).

Figure 1.4 documents that the climate system is undergoing a comprehensive set of changes. It shows a selection of key indicators of change through the instrumental era that are assessed and presented in the subsequent chapters of this report. Annual mean values are shown as stripes, with colours indicating their value. The transitions from one colour to another over time illustrate how conditions are shifting in all components of the climate system. For these particular indicators, the observed changes go beyond the yearly and decadal variability of the climate system. In this Report, this is termed an 'emergence' of the climate signal (see Section 1.4.2 and FAQ 1.2).

Warming of the climate system is most commonly presented through the observed increase in global mean surface temperature (GMST). Taking a baseline of 1850–1900, GMST change until present (2011–2020) is 1.09 °C (0.95–1.20 °C) (see Chapter 2, Section 2.3, Cross-Chapter Box 2.3). This evolving change has been documented in previous Assessment Reports, with each reporting a higher total global temperature change (see Section 1.3, Cross-Chapter Box 1.2). The total change in Global Surface Air Temperature (GSAT; see Section 1.4.1 and Cross-Chapter Box 2.3 in Chapter 2) attributable to anthropogenic activities is assessed to be consistent with the observed change in GSAT (see Chapter 3, Section 3.3)[1].

Similarly, atmospheric concentrations of a range of greenhouse gases are increasing. Carbon dioxide (CO_2, shown in Figure 1.4 and Figure 1.5a), found in AR5 and earlier reports to be the current strongest driver of anthropogenic climate change, has increased from 285.5 ± 2.1 ppm in 1850 to 409.9 ± 0.4 ppm in 2019; concentrations of methane (CH_4), and nitrous oxide (N_2O) have increased as well (see Chapter 2, Sections 2.2, Chapter 5, section 5.2, and Annex V). These observed changes are assessed to be in line with known anthropogenic and natural emissions, when accounting for observed and inferred uptake by land, ocean, and biosphere respectively (see Chapter 5, Section 5.2), and are a key source of anthropogenic changes to the global energy balance (or radiative forcing; see Chapter 2, Section 2.2 and Chapter 7, Section 7.3).

The hydrological (or water) cycle is also changing and is assessed to be intensifying, through a higher exchange of water between the surface and the atmosphere (see Chapter 3, Section 2.3 and Chapter 8, Section 8.3). The resulting regional patterns of changes to precipitation are, however, different from surface temperature change, and interannual variability is larger, as illustrated in Figure 1.4. Annual land area mean precipitation in the Northern Hemisphere temperate regions has increased, while the sub-tropical dry regions have experienced a decrease in precipitation in recent decades (see Chapter 2, Section 2.3).

The cryosphere is undergoing rapid changes, with increased melting and loss of frozen water mass in most

[1] Note that GMST and GSAT are physically distinct but closely related quantities, see Section 1.4.1 and Cross-Chapter Box 2.3 in Chapter 2.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

regions. This includes all frozen parts of the globe, such as terrestrial snow, permafrost, sea ice, glaciers, freshwater ice, solid precipitation, and the ice sheets covering Greenland and Antarctica (see Chapter 9; SROCC, IPCC, 2019b). Figure 1.4 illustrates how, globally, glaciers have been increasingly losing mass for the last fifty years. The total glacier mass in the most recent decade (2010-2019) was the lowest since the beginning of the 20th century. (See Chapter 2, Section 2.3 and Chapter 9, Section 9.5).

The global ocean has warmed unabatedly since at least 1970 (Sections 1.3, 2.3, 9.2; SROCC, IPCC, 2019b) . Figure 1.4 shows how the averaged ocean heat content is steadily increasing, with a total increase of [0.28–0.55] yottajoule (10^{24} joule) between 1971 and 2018. (see Chapter 9, Section 9.2). In response to this ocean warming, as well as to the loss of mass from glaciers and ice sheets, the global mean sea level (GMSL) has risen by 0.20 [0.15 to 0.25] metres between 1900 and 2018. GMSL rise has accelerated since the late 1960s. (See Chapter 9, Section 9.6).

Overall, the changes in these selected climatic indicators have progressed beyond the range of natural year-to-year variability (see Chapters 2, 3, 8, and 9, and further discussion in Sections 1.2.1.2 and 1.4.2). The indicators presented in Figure 1.4 document a broad set of concurrent and emerging changes across the physical climate system. All indicators shown here, along with many others, are further presented in the coming chapters, together with a rigorous assessment of the supporting scientific literature. Later chapters (Chapter 10, 11, 12, and the Atlas) present similar assessments at the regional level, where observed changes do not always align with the global mean picture shown here.

[START FIGURE 1.4 HERE]

Figure 1.4: Changes are occurring throughout the climate system. Left: Main realms of the climate system: atmosphere, biosphere, cryosphere, and ocean. Right: Six key indicators of ongoing changes since 1850, or the start of the observational or assessed record, through 2018. Each stripe indicates the global (except for precipitation which shows two latitude band means), annual mean anomaly for a single year, relative to a multi-year baseline (except for CO_2 concentration and glacier mass loss, which are absolute values). Grey indicates that data are not available. Datasets and baselines used are: (1) CO_2: Antarctic ice cores (Lüthi et al., 2008; Bereiter et al., 2015) and direct air measurements (Tans and Keeling, 2020) (see Figure 1.5 for details); (2) precipitation: Global Precipitation Climatology Centre (GPCC) V8 (updated from Becker et al. 2013), baseline 1961-1990 using land areas only with latitude bands 33°N–66°N and 15°S–30°S; (3) glacier mass loss: Zemp et al., 2019; (4) global surface air temperature (GMST): HadCRUT5 (Morice et al., 2021), baseline 1961–1990; (5) sea level change: (Dangendorf et al., 2019), baseline 1900–1929; (6) ocean heat content (model-observation hybrid): Zanna et al., (2019), baseline 1961–1990. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.4 HERE]

1.2.1.2 Long-term perspectives on anthropogenic climate change

Paleoclimate archives (e.g. ice cores, corals, marine and lake sediments, speleothems, tree rings, borehole temperatures, soils) permit the reconstruction of climatic conditions before the instrumental era. This establishes an essential long-term context for the climate change of the past 150 years and the projected changes in the 21st century and beyond (IPCC, 2013a; Masson-Delmotte et al., 2013) Chapter 3). Figure 1.5 shows reconstructions of three key indicators of climate change over the past 800,000 years[2] – atmospheric CO_2 concentrations, global mean surface temperature (GMST) and global mean sea level (GMSL) –

[2] as old as the longest continuous climate records based on the ice core from EPICA Dome Concordia (Antarctica). Polar ice cores are the only paleoclimatic archive providing direct information on past greenhouse gas concentrations.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

comprising at least eight complete glacial-interglacial cycles (EPICA Community Members, 2004; Jouzel et al., 2007) that are largely driven by oscillations in the Earth's orbit and consequent feedbacks on multi-millennial time scales (Berger, 1978; Laskar et al., 1993). The dominant cycles – recurring approximately every 100,000 years – can be found imprinted in the natural variations of these three key indicators. Before industrialisation, atmospheric CO_2 concentrations varied between 174 ppm and 300 ppm, as measured directly in air trapped in ice at Dome Concordia, Antarctica (Bereiter et al., 2015; Nehrbass-Ahles et al., 2020). Relative to 1850–1900, the reconstructed GMST changed in the range of -6 to +1°C across these glacial-interglacial cycles (see Chapter 2, Section 2.3.1 for an assessment of different paleo reference periods). GMSL varied between about -130 m during the coldest glacial maxima and +5 to +25 m during the warmest interglacial periods (Spratt and Lisiecki, 2016; Chapter 2). They represent the amplitudes of natural, global-scale climate variations over the last 800,000 years prior to the influence of human activity. Further climate information from a variety of paleoclimatic archives are assessed in Chapters 2, 5, 7, 9.

Paleoclimatic information also provides a long-term perspective on rates of change of these three key indicators. The rate of increase in atmospheric CO_2 observed over 1919-2019 CE is one order of magnitude higher than the fastest CO_2 fluctuations documented during the last glacial maximum and the last deglacial transition in high-resolution reconstructions from polar ice cores (Marcott et al., 2014, see Chapter 2, Section 2.2.3.2.1). Current multi-decadal GMST exhibit a higher rate of increase than over the past two thousand years (PAGES 2k Consortium, 2019; Chapter 2, Section 2.3.1.1.2), and in the 20th century GMSL rise was faster than during any other century over the past three thousand years (Chapter 2, Section 2.3.3.3).

[START FIGURE 1.5 HERE]

Figure 1.5: Long-term context of anthropogenic climate change based on selected paleoclimatic reconstructions over the past 800,000 years for three key indicators: atmospheric CO_2 concentrations, Global Mean Surface Temperature (GMST), and Global Mean Sea Level (GMSL). a) Measurements of CO_2 in air enclosed in Antarctic ice cores (Lüthi et al., 2008; Bereiter et al., 2015 [a compilation]; uncertainty ±1.3ppm; see Chapter 2, Section 2.2.3 and Chapter 5, Section 5.1.2 for an assessment) and direct air measurements (Tans and Keeling, 2020; uncertainty ±0.12 ppm). Projected CO_2 concentrations for five Shared Socioeconomic Pathways (SSP) scenarios are indicated by dots on the right-hand side panels of the figure (grey background) (Meinshausen et al., 2020; SSPs are described in Section 1.6). b) Reconstruction of GMST from marine paleoclimate proxies (light grey: Snyder (2016); dark grey: Hansen et al. (2013); see Chapter 2, Section 2.3.1 for an assessment). Observed and reconstructed temperature changes since 1850 are the AR6 assessed mean (referenced to 1850–1900; Box TS.3; 2.3.1.1); dots/whiskers on the right-hand side panels of the figure (grey background) indicate the projected mean and ranges of warming derived from Coupled Model Intercomparison Project Phase 6 (CMIP6) SSP-based (2081–2100) and Model for the Assessment of Greenhouse Gas Induced Climate Change (MAGICC7) (2300) simulations (Chapter 4, Tables 4.5 and 4.9). c) Sea level changes reconstructed from a stack of oxygen isotope measurements on seven ocean sediment cores (Spratt and Lisiecki, 2016; see Chapter 2, Section 2.3.3.3 and Chapter 9, Section 9.6.2 for an assessment). The sea level record from 1850 to 1900 is from Kopp et al. (2016), while the 20th century record is an updated ensemble estimate of GMSL change (Palmer et al., 2021; see also Chapter 2, Section 2.3.3.3 and Chapter 9, Section 9.6.1.1). Dots/whiskers on the right-hand side panels of the figure (grey background) indicate the projected median and ranges derived from SSP-based simulations (2081–2100: Chapter 9, Table 9.9; 2300: Chapter 9, Section 9.6.3.5). Best estimates (dots) and uncertainties (whiskers) as assessed by Chapter 2 are included in the left and middle panels for each of the three indicators and selected paleo-reference periods used in this report (CO_2: Chapter 2, Table 2.1; GMST: Chapter 2, Section 2.3.1.1 and Cross-Chapter Box 2.3, Table 1 in Chapter 2; GMSL: Chapter 2, Section 2.3.3.3 and Chapter 9, Section 9.6.2. See also Cross-Chapter Box 2.1 in Chapter 2). Selected paleo-reference periods: LIG – Last Interglacial; LGM – Last Glacial Maximum; MH – mid-Holocene (Cross-Chapter Box 2.1, Table 1 in Chapter 2). The non-labelled best estimate in panel c) corresponds to the sea level high-stand during Marine Isotope Stage 11, about 410,000 years ago (see Chapter 9, Section 9.6.2). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.5 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Paleoclimate reconstructions also shed light on the causes of these variations, revealing processes that need to be considered when projecting climate change. The paleorecords show that sustained changes in global mean temperature of a few degrees Celsius are associated with increases in sea level of several tens of metres (Figure 1.5). During two extended warm periods (interglacials) of the last 800,000 years, sea level is estimated to have been at least six metres higher than today (Chapter 2; Dutton et al., 2015). During the last interglacial, sustained warmer temperatures in Greenland preceded the peak of sea level rise (Figure 5.15 in Masson-Delmotte et al., 2013). The paleoclimate record therefore provides substantial evidence directly linking warmer GMST to substantially higher GMSL.

GMST will remain above present-day levels for many centuries even if net CO_2 emissions are reduced to zero, as shown in simulations with coupled climate models (Plattner et al., 2008; Section 12.5.3 in Collins et al., 2013; Zickfeld et al., 2013; MacDougall et al., 2020; Chapter 4, Section 4.7.1). Such persistent warm conditions in the atmosphere represent a multi-century commitment to long-term sea level rise, summer sea ice reduction in the Arctic, substantial ice sheet melting, potential ice sheet collapse, and many other consequences in all components of the climate system (Clark et al., 2016; Pfister and Stocker, 2016; Fischer et al., 2018; see also Chapter 9, Section 9.4) (Figure 1.5).

Paleoclimate records also show centennial- to millennial-scale variations, particularly during the ice ages, which indicate rapid or abrupt changes of the Atlantic Meridional Overturning Circulation (AMOC; see Chapter 9, Section 9.2.3.1) and the occurrence of a 'bipolar seesaw' (opposite-phase surface temperature changes in both hemispheres; Stocker and Johnsen, 2003; EPICA Community Members, 2006; Members WAIS Divide Project et al., 2015; Lynch-Stieglitz, 2017; Pedro et al., 2018; Weijer et al., 2019, see Chapter 2, Section 2.3.3.4.1). This process suggests that instabilities and irreversible changes could be triggered if critical thresholds are passed (Section 1.4.4.3). Several other processes involving instabilities are identified in climate models (Drijfhout et al., 2015), some of which may now be close to critical thresholds (Joughin et al., 2014; Section 1.4.4.3; see also Chapters 5, 8 and 9 regarding tipping points).

Based on Figure 1.5, the reconstructed, observed and projected ranges of changes in the three key indicators can be compared. By the first decade of the 20th century, atmospheric CO_2 concentrations had already moved outside the reconstructed range of natural variation over the past 800,000 years. On the other hand, global mean surface temperature and sea level were higher than today during several interglacials of that period (Chapter 2, Section 2.3.1, Figure 2.34 and Section 2.3.3). Projections for the end of the 21st century, however, show that GMST will have moved outside of its natural range within the next few decades, except for the strong mitigation scenarios (Section 1.6). There is a risk that GMSL may potentially leave the reconstructed range of natural variations over the next few millennia (Clark et al., 2016; Chapter 9, Section 9.6.3.5; SROCC (IPCC, 2019b). In addition, abrupt changes can not be excluded (Section 1.4.4.3).

An important time period in the assessment of anthropogenic climate change is the last 2000 years. Since AR5, new global datasets have emerged, aggregating local and regional paleorecords (PAGES 2k Consortium, 2013, 2017, 2019; McGregor et al., 2015; Tierney et al., 2015; Abram et al., 2016; Hakim et al., 2016; Steiger et al., 2018; Brönnimann et al., 2019b). Before the global warming that began around the mid-19th century (Abram et al., 2016), a slow cooling in the Northern Hemisphere from roughly 1450 to 1850 is consistently recorded in paleoclimate archives (PAGES 2k Consortium, 2013; McGregor et al., 2015). While this cooling, primarily driven by an increased number of volcanic eruptions (PAGES 2k Consortium, 2013; Owens et al., 2017; Brönnimann et al., 2019b; Chapter 3, Section 3.3.1), shows regional differences, the subsequent warming over the past 150 years exhibits a global coherence that is unprecedented in the last 2000 years (Neukom et al., 2019).

The rate, scale, and magnitude of anthropogenic changes in the climate system since the mid-20th century suggested the definition of a new geological epoch, the Anthropocene (Crutzen and Stoermer, 2000; Steffen et al., 2007), referring to an era in which human activity is altering major components of the Earth system and leaving measurable imprints that will remain in the permanent geological record (IPCC, 2018) (Figure 1.5). These alterations include not only climate change itself, but also chemical and biological changes in the Earth system such as rapid ocean acidification due to uptake of anthropogenic carbon dioxide, massive destruction of tropical forests, a worldwide loss of biodiversity and the sixth mass extinction of species

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(Hoegh-Guldberg and Bruno, 2010; Ceballos et al., 2017; IPBES, 2019). According to the key messages of the last global assessment of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES, 2019), climate change is a 'direct driver that is increasingly exacerbating the impact of other drivers on nature and human well-being', and 'the adverse impacts of climate change on biodiversity are projected to increase with increasing warming'.

1.2.2 The policy and governance context

The contexts of both policymaking and societal understanding about climate change have evolved since the AR5 was published (2013–2014). Increasing recognition of the urgency of the climate change threat, along with still-rising emissions and unresolved issues of mitigation and adaptation, including aspects of sustainable development, poverty eradication and equity, have led to new policy efforts. This section summarizes these contextual developments and how they have shaped, and been used during the preparation of this Report.

IPCC reports and the UN Framework Convention on Climate Change (UNFCCC). The IPCC First Assessment Report (FAR, IPCC, 1990a) provided the scientific background for the establishment of the United Nations Framework Convention on Climate Change (UNFCCC, 1992), which committed parties to negotiate ways to 'prevent dangerous anthropogenic interference with the climate system' (the ultimate objective of the UNFCCC). The Second Assessment Report (SAR, IPCC, 1995a) informed governments in negotiating the Kyoto Protocol (1997), the first major agreement focusing on mitigation under the UNFCCC. The Third Assessment report (TAR, IPCC, 2001a) highlighted the impacts of climate change and need for adaptation and introduced the treatment of new topics such as policy and governance in IPCC reports. The Fourth and Fifth Assessment Reports (AR4, IPCC, 2007a; AR5, IPCC, 2013a) provided the scientific background for the second major agreement under the UNFCCC: the Paris Agreement (2015), which entered into force in 2016.

The Paris Agreement (PA). Parties to the PA commit to the goal of limiting global average temperature increase to 'well below 2°C above pre-industrial levels, and to pursue efforts to limit the temperature increase to 1.5°C in order to 'significantly reduce the risks and impacts of climate change'. In AR6, as in many previous IPCC reports, observations and projections of changes in global temperature are expressed relative to 1850-1900 as an approximation for pre-industrial levels (Cross-Chapter Box 1.2).

The PA further addresses mitigation (Article 4) and adaptation to climate change (Article 7), as well as loss and damage (Article 8), through the mechanisms of finance (Article 9), technology development and transfer (Article 10), capacity-building (Article 11) and education (Article 12). To reach its long-term temperature goal, the PA recommends 'achieving a balance between anthropogenic emissions by sources and removals by sinks of greenhouse gases in the second half of this century', a state commonly described as 'net zero' emissions (Article 4) (Section 6, Box 1.4). Each Party to the PA is required to submit a Nationally Determined Contribution (NDC) and pursue, on a voluntary basis, domestic mitigation measures with the aim of achieving the objectives of its NDC (Article 4).

Numerous studies of the NDCs submitted since adoption of the PA in 2015 (Fawcett et al., 2015; UNFCCC, 2015, 2016; Lomborg, 2016; Rogelj et al., 2016, 2017; Benveniste et al., 2018; Gütschow et al., 2018; United Nations Environment Programme (UNEP), 2019) conclude that they are insufficient to meet the Paris temperature goal. In the present IPCC Sixth Assessment cycle, a Special Report on Global Warming of 1.5°C (SR1.5, IPCC, 2018) assessed *high agreement* that current NDCs 'are not in line with pathways that limit warming to 1.5°C by the end of the century'. The PA includes a ratcheting mechanism designed to increase the ambition of voluntary national pledges over time. Under this mechanism, NDCs will be communicated or updated every five years. Each successive NDC will represent a 'progression beyond' the 'then current' NDC and reflect the 'highest possible ambition' (Article 4). These updates will be informed by a five-yearly periodic review including the 'Structured Expert Dialogue' (SED), as well as a 'global stocktake', to assess collective progress toward achieving the PA long-term goals. These processes will rely upon the assessments prepared during the IPCC sixth assessment cycle (e.g., Schleussner et al., 2016b;

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Chapter Box 1.1).

The Structured Expert Dialogue (SED). Since AR5, the formal dialogue between the scientific and policy communities has been strengthened through a new science-policy interface, the Structured Expert Dialogue (SED). The SED was established by UNFCCC to support the work of its two subsidiary bodies, the Subsidiary Body for Scientific and Technological Advice (SBSTA) and the Subsidiary Body for Implementation (SBI). The first SED aimed to 'ensure the scientific integrity of the first periodic review' of the UNFCCC, the 2013-2015 review. The Mandate of the periodic review is to 'assess the adequacy of the long-term (temperature) goal in light of the ultimate objective of the convention' and the 'overall progress made towards achieving the long-term global goal, including a consideration of the implementation of the commitments under the Convention'.

The SED of the first periodic review (2013-2015) provided an important opportunity for face-to-face dialogue between decision makers and experts on review themes, based on 'the best available scientific knowledge, including the assessment reports of the IPCC'. That SED was instrumental in informing the long-term global goal of the PA and in providing the scientific argument of the consideration of limiting warming to 1.5°C warming (Fischlin et al., 2015; Fischlin, 2017). The SED of the second periodic review, initiated in the second half of 2020, focuses on, inter alia, 'enhancing Parties' understanding of the long-term global goal and the scenarios towards achieving it in the light of the ultimate objective of the Convention'. The second SED provides a formal venue for the scientific and the policy communities to discuss the requirements and benchmarks to achieve the 'long-term temperature goal' (LTTG) of 1.5°C and well below 2°C global warming. The discussions also concern the associated timing of net zero emissions targets and the different interpretations of the PA LTTG, including the possibility of overshooting the 1.5° C warming level before returning to it by means of negative emissions (e.g., Schleussner and Fyson, 2020; Section 1.6). The second periodic review is planned to continue until November 2022 and its focus includes the review of the progress made since the first review, with minimising 'possible overlaps' and profiting from 'synergies with the Global Stocktake'.

[START CROSS-CHAPTER BOX 1.1 HERE]

Cross-Chapter Box 1.1: The WGI contribution to the AR6 and its potential relevance for the global stocktake

Contributing Authors: Malte Meinshausen (Australia/Germany), Gian-Kasper Plattner (Switzerland), Aïda Diongue-Niang (Senegal), Francisco Doblas-Reyes (Spain), David Frame (New Zealand), Nathan Gillett (Canada/UK), Helene Hewitt (UK), Richard Jones (UK), Hong Liao (China), Jochem Marotzke (Germany), James Renwick (New Zealand), Joeri Rogelj (Belgium), Maisa Rojas (Chile), Sonia I. Seneviratne (Switzerland), Claudia Tebaldi (USA), Blair Trewin (Australia)

The global stocktake under the Paris Agreement (PA) evaluates the collective progress of countries' actions towards attaining the Agreement's purpose and long-term goals every five years. The first global stocktake is due in 2023, and then every five years thereafter, unless otherwise decided by the Conference of the Parties. The purpose and long-term goals of the PA are captured in Article 2: to 'strengthen the global response to the threat of climate change, in the context of sustainable development and efforts to eradicate poverty, including by': *mitigation*[3], specifically, 'holding the increase in the global average temperature to well below 2°C above pre-industrial levels and to pursue efforts to limit the temperature increase to 1.5°C above pre-industrial levels, recognizing that this would significantly reduce

[3] the labels of mitigation, adaptation and means of implementation and support are here provided for reader's guidance only, with no presumption about the actual legal content of the paragraphs and to which extent they encompass mitigation, adaptation and means of implementation in its entirety.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the risks and impacts of climate change'; *adaptation*, that is, 'Increasing the ability to adapt to the adverse impacts of climate change and foster climate resilience and low greenhouse gas emissions development, in a manner that does not threaten food production'; and *means of implementation and support*, that is, 'Making finance flows consistent with a pathway towards low greenhouse gas emissions and climate-resilient development'.

The PA further specifies that the stocktake shall be undertaken in a 'comprehensive and facilitative manner, considering mitigation, adaptation and the means of implementation and support, and in the light of equity and the best available science' (Article 14).

The sources of input envisaged for the global stocktake include the 'latest reports of the Intergovernmental Panel on Climate Change' as a central source of information[4]. The global stocktake is one of the key formal avenues for scientific inputs into the UNFCCC and PA negotiation process alongside, for example, the Structured Expert Dialogues under the UNFCCC[5] (Section 1.2.2).

The WGI assessment provides a wide range of information potentially relevant for the global stocktake, complementing the IPCC AR6 Special Reports, the contributions from WGII and WGIII and the Synthesis Report. This includes the state of greenhouse gas emissions and concentrations, the current state of the climate, projected long-term warming levels under different scenarios, near-term projections, the attribution of extreme events, and remaining carbon budgets. Cross-Chapter Box 1.1, Table 1 provide pointers to the in-depth material that WGI has assessed and may be relevant for the global stocktake.

The following tabularised overview of potentially relevant information from the WGI contribution for the global stocktake is structured into three sections: the current state of the climate, the long-term future, and the near-term. These sections and their order align with the three questions of the Talanoa dialogue, launched during COP23 based on the Pacific concept of talanoa[6]: '*Where are we', 'Where do we want to go'* and '*How do we get there?'*.

[START CROSS-CHAPTER BOX 1.1, TABLE 1 HERE]

Cross-Chapter Box 1.1, Table 1: WGI assessment findings and their potential relevance for the global stocktake. The table combines information assessed in this report that could potentially be relevant for the global stocktake process. Section 1 focuses on the current state of the climate and its recent past. Section 2 focuses on long-term projections in the context of the PA's 1.5°C and 2.0°C goals and on progress towards net zero greenhouse gas emissions. Section 3 considers challenges and key insights for mitigation and adaptation in the near term from a WGI perspective. Further Information on potential relevance of the aspects listed here in terms of, for example, impacts and socio-economic aspects can be found in the WGII and WGIII reports

Section 1: State of the Climate – '*Where are we?'* *WGI assessment to inform about past changes in the climate system, current climate and committed changes.*

[6] Decision 1/CP.23, in FCCC/CP/2017/L.13, available at https://unfccc.int/resource/docs/2017/cop23/eng/l13.pdf

How much warming have we observed in global mean surface air temperatures?	Cross-Chapter Box 1.2; Cross-Chapter Box 2.3; 2.3.1.1, especially 2.3.1.1.3	Knowledge about the current warming relative to pre-industrial levels allows us to quantify the remaining distance to the PA goal of keeping global mean temperatures well below 2°C above pre-industrial level or pursue best efforts to limit warming to 1.5°C above pre-industrial level. Many of the report's findings are provided against a proxy for pre-industrial temperature levels with Cross-Chapter Box 1.2 examining the difference between pre-industrial levels and the 1850–1900 period.
How much has the ocean warmed?	2.3.3.1, 9.2.1.1; Box 9.1; 7.2; Box 7.2	A warming ocean can affect marine life (e.g., coral bleaching) and also are among the main contributors to long-term sea level rise (thermal expansion). Marine heatwaves can accentuate the impacts of ocean warming on marine ecosystems. Also, knowing the heat uptake of the ocean helps to better understand the response of the climate system and hence helps to project future warming.
How much have the land areas warmed and how has precipitation changed?	2.3.4; 5.4.3; 5.4.8; 8.2.1; 8.2.3; 8.5.1;	A stronger than global-average warming over land, combined with changing precipitation patterns, and/or increased aridity in some regions (like the Mediterranean) can severely affect land ecosystems and species distributions, the terrestrial carbon cycle and food production systems. Amplified warming in the Arctic can enhance permafrost thawing, which in turn can result in overall stronger anthropogenic warming (a positive feedback loop). Intensification of heavy precipitation events can cause more severe impacts related to flooding.
How did the sea ice area change in recent decades in both the Arctic and Antarctic?	2.3.2.1.1; 2.3.2.1.2; 9.3; Cross-Chapter Box 10.1; 12.4.9	Sea ice area influences mass and energy (ice-albedo, heat and momentum) exchange between the atmosphere and the ocean, and its changes in turn impact polar life, adjacent land and ice masses and complex dynamical flows in the atmosphere. The loss of a year-round sea-ice cover in the Arctic can severely impact Arctic ecosystems, affect the livelihood of First Nations in the Arctic, and amplify Arctic warming with potential consequences for the warming of the surrounding permafrost regions and ice sheets.
How much have atmospheric CO_2 and other GHG concentrations increased?	2.2.3; 2.2.4; 5.1.1; 5.2.2; 5.2.3; 5.2.4	The main human influence on the climate is via combustion of fossil fuels and land use-change-related CO_2 emissions, the principal causes of increased CO_2 concentrations since the pre-industrial period. Historical observations indicate that current atmospheric concentrations are unprecedented within at least the last 800,000 years. An understanding of historical fossil fuel emissions and the carbon cycle interactions, as well as CH_4 and N_2O sinks and sources are crucial for better estimates of future GHG emissions compatible with the PA's long-term goals.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

How much did sea level rise in past centuries and how large is the long-term commitment?	2.3.3.3; 9.6.1; 9.6.2; FAQ 9.1; Box 9.1; 9.6.3; 9.6.4	Sea level rise is a comparatively slow consequence of a warming world. Historical warming committed the world already to long-term sea level rise that is not reversed in even the lowest emissions scenarios (such as 1.5°C), which come with a multimeter sea level commitment. Regional sea level change near the coastlines differs from global-mean sea level change due to vertical land movement, ice mass changes, and ocean dynamical changes.
How much has the ocean acidified and how much oxygen have they lost?	2.3.4.3; 2.3.4.2; 5.3	Ocean acidification is affecting marine life, especially organisms that build calciferous shells and structures (e.g., coral reefs). Together with less oxygen in upper ocean waters and increasingly widespread oxygen minimum zones and in addition to ocean warming, this poses adaptation challenges for coastal and marine ecosystems and their services, including seafood supply.
How much of the observed warming was due to anthropogenic influences?	3.3.1	To monitor progress toward the PA's long-term goals it is important to know how much of the observed warming is due to human activities. Chapter 3 assesses human-induced warming in global mean near-surface air temperature for the decade 2010–2019, relative to 1850–1900 with associated uncertainties, based on detection and attribution studies. This estimate can be compared with observed estimates of warming for the same decade reported in Chapter 2, and is typically used to calculate carbon budgets consistent with remaining below a particular temperature threshold.
How much has anthropogenic influence changed other aspects of the climate system?	3.3.2; 3.3.3; 3.4; 3.5; 3.6; 3.7; 8; 12; 10.4	Climate change impacts are driven by changes in many aspects of the climate system, including changes in the water cycle, atmospheric circulation, ocean, cryosphere, biosphere and modes of variability, and to better plan climate change adaptation it is relevant to know which observed changes have been driven by human influence.
How much are anthropogenic emissions contributing to changes in the severity and frequency of extreme events?	9.6.4; 11.3-11.8; 12.3; Cross-Chapter Box 3.2; 1.5; Cross-Chapter Box 1.3	Adaptation challenges are often accentuated in the face of extreme events, including floods, droughts, bushfires, and tropical cyclones. For agricultural management, infrastructure planning, and designing for climate resilience it is relevant to know whether extreme events will become more frequent in the near future. In that respect it is important to understand whether observed extreme events are part of a natural background variability or caused by past anthropogenic emissions. This attribution of extreme events is therefore key to understanding current events, as well as to better project the future evolution of these events, such as temperature extremes; heavy precipitation; floods; droughts; extreme storms and compound events; extreme sea level. Also, loss and damage events are often related to extreme events, which means that future disasters can be fractionally attributed to

ACCEPTED VERSION SUBJECT TO FINAL EDITS

		past human emissions

Section 2: Long-term climate futures. – *'Where do we want to go?'*
WGI assessment to inform how long-term climate change could unfold depending on chosen emission futures.

Question	Chapter	Potential Relevance and Explanatory Remarks
How are climate model projections used to project the range of future global and regional climate changes?	Box 4.1; 3.8.2; Cross-Chapter Box 3.1; 10.3; 10.4; 12.4	The scientific literature provides new insights in a developing field of scientific research regarding evaluating model performance and weighting. This can lead to more constrained projection ranges for a given scenario and some variables, which take into account the performance of climate models and interdependencies among them. These techniques have a strong relevance to quantifying future uncertainties, for example regarding the likelihood of the various scenarios exceeding the PA's long-term temperature goals of 1.5°C or 2°C.
If emission scenarios are pursued that achieve mitigation goals by 2050, what are the differences in climate over the 21st century compared to emission scenarios where no additional climate policies are implemented?	1.2.2; 4.6, FAQ 4.2, 12.4, 9, 11; Atlas; Interactive Atlas;	Understanding of the response to a change of anthropogenic emissions is important to estimate the scale and timing of mitigation compatible with the PA's long-term goals. The new generation of scenarios spans the response space from very low emission scenarios (SSP1-1.9) under the assumption of accelerated and effective climate policy implementation, to very high emission scenarios in the absence of additional climate policies (SSP3-7.0 or SSP5-8.5). It can be informative to place current NDCs and their emission mitigation pledges within this low and high-end scenario range, that is, in the context of medium-high emission scenarios (RCP4.5, RCP6.0 or SSP4-6.0). Climate response differences between those future medium or high emission scenarios and those compatible with the PA's long-term temperature goals can help inform policymakers about the corresponding adaptation challenges.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

What is the climatic effect of net zero GHG emissions and a balance between anthropogenic sources and anthropogenic sinks?	Box 1.4; 4.7.2; 5.2.2; 5.2.3 and 5.2.4; 7.6	Understanding the long-term climate effect of global emission levels, including the effect of net zero emission targets adopted by countries as part of their long-term climate strategies, can be important when assessing whether the collective level of mitigation action is consistent with long-term goals of the PA. Understanding the dynamics of natural sources of CO_2, CH_4 and N_2O is a fundamental prerequisite to derive climate projections. Net zero GHG emissions, that is, the balance between anthropogenic sources and anthropogenic sinks of CO_2 and other greenhouse gases, will halt human-induced global warming and/or lead to slight reversal below peak warming levels. Net zero CO_2 emissions will approximately lead to a stabilisation of CO_2-induced global warming.
What is the remaining carbon budget that is consistent with the PA's long-term temperature goals?	5.5	The remaining carbon budget provides an estimate of how much CO_2 can still be emitted into the atmosphere by human activities while keeping global mean surface temperature to a specific warming level. It thus provides key geophysical information about emissions limits consistent with limiting global warming to well below 2°C above pre-industrial levels and to pursue efforts to limit the temperature increase to 1.5°C. Remaining carbon budgets can be seen in the context of historical CO_2 emissions to date. The concept of the transient climate response to cumulative emissions of CO_2 (TCRE) indicates that one tonne of CO_2 has the same effect on global warming irrespective of whether it is emitted in the past, today, or in the future. In contrast, the global warming from short-lived climate forcers is dependent on their rate of emission rather than their cumulative emission.
What is our current knowledge on the 'Reasons for Concern' related to the PA's long-term temperature goals and higher warming levels?	Cross-Chapter Box 12.1; with individual domains discussed in 2.3.3, 3.5.4, 4.3.2; 5.3; 8.4.1; 9.4.2, 9.5; 11; 12	Synthesis information on projected changes in indices of climatic impact-drivers feeds into different 'Reasons for Concern'. Where possible, an explicit transfer function between different warming levels and indices quantifying characteristics of these hazards is provided, or the difficulties in doing so documented. Those indices include Arctic sea ice area in September; global average change in ocean acidification; volume of glaciers or snow cover; ice volume change for the West Antarctic Ice Sheet (WAIS) and Greenland Ice Sheet (GIS); Atlantic Meridional Overturning Circulation (AMOC) strength ; amplitude and variance of El Niño Southern Oscillation (ENSO) mode (Nino3.4 index); and weather and climate extremes.
What are the climate effects and air pollution co-benefits of rapid decarbonisation due to the reduction of co-emitted short-lived climate forcers (SLCF)?	6.6.3 ; 6.7.3 ; Box 6.2	Understanding to what degree rapid decarbonisation strategies bring about reduced air pollution due to reductions in co-emitted short-lived climate forcers can be useful to consider integrated and/or complementary policies, with synergies for pursuing the PA goals, the World Health Organization (WHO) air quality guidelines and the Sustainable Development Goals (SDGs).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

What are the Equilibrium Climate Sensitivity, the Transient Climate Response, and Transient Climate Response to Emissions and what do these indicators tell us about expected warming over the 21st century under various scenarios?	Box 4.1; 5.4, 5.5.1, 7.5	Equilibrium Climate Sensitivity (ECS) measures the long-term global-mean warming in response to doubling CO_2 concentrations from pre-industrial levels, while Transient Climate Response (TCR) also takes into account the inertia of the climate system and is an indicator for the near- and medium-term warming. TCRE is similar to TCR, but asks the question of what is the implied warming is in response to cumulative CO_2 emissions (rather than CO_2 concentration changes). The higher the ECS, TCR or TCRE, the lower are the greenhouse gas emissions that are consistent with the PA's long-term temperature goals.
What is the Earth's energy imbalance and why does it matter?	7.2.2	The current global energy imbalance implies that one can expect additional warming before the Earth's climate system attains equilibrium with the current level of concentrations and radiative forcing. Note though, that future warming commitments can be different depending on how future concentrations and radiative forcing change.
What are the regional and long-term changes in precipitation, evaporation and runoff?	8.4.1, 8.5; 8.6; 10.4; 10.6; 12.4; 11.4; 11.9; 11.6; 11.7; Atlas; Interactive Atlas	Changes in regional precipitation – in terms of both extremes and long-term averages – are important for estimating adaptation challenges. Projected changes of precipitation minus evaporation (P-E) are closely related to surface water availability and drought probability. Understanding water cycle changes over land, including seasonality, variability and extremes, and their uncertainties, is important to estimate a broad range of climate impacts and adaptation, including food production, water supply and ecosystem functioning.
Are we committed to irreversible sea level rise and what is the expected sea level rise by the end of the century if we pursue strong mitigation or high emission scenarios?	4.7.2; 9.6.3; 9.6.4; 12.4; Interactive Atlas	Unlike many regional climate responses, global-mean sea level keeps rising even in the lowest scenarios and is not halted when warming is halted. This is due to the long timescales on which ocean heat uptake, glacier melt, ice sheets react to temperature changes. Tipping points and thresholds in polar ice sheets need to be considered. Thus, sea level rise commitments and centennial-scale irreversibility of ocean warming and sea level rise are important for future impacts under even the lowest of the emission scenarios.
Can we project future climate extremes under various global warming levels in the long term?	11, 12.4; Interactive Atlas	Projections of future weather and climate extreme events and their regional occurrence, including at different global warming levels, are important for adaptation and disaster risk reduction. The attribution of these extreme events to natural variability and human-induced changes can be of relevance for both assessing adaptation challenges and issues of loss and damage.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

What is the current knowledge of potential surprises, abrupt changes, tipping points and low-likelihood, high impact events related to different levels of future emissions or warming?	1.4.4; 4.7.2; 4.8; 5.4.8; Box 5.1; 8.5.3.2; 8.6.2; Box 9.4; 11.2.4; Cross-Chapter Box 4.1; Cross-Chapter Box 12.1	From a risk perspective, it is useful to have information of lower probability events and system changes, if they could potentially result in high impacts, given the dynamic interactions between climate-related hazards and socio-economic drivers (exposure, vulnerability of the affected human or ecological systems). Examples include permafrost thaw, CH_4 clathrate feedbacks, ice sheet mass loss, ocean turnover circulation changes, either accelerating warming globally or yielding particular regional responses and impacts.

Section 3: The near term. – '*How do we get there?'*
WGI assessment to inform near-term adaptation and mitigation options

Questions	**Chapter**	**Potential Relevance and Explanatory Remarks**
What are projected key climate indices under low, medium and high emission scenarios in the near term, that is, the next 20 years?	4.3; 4.4; FAQ 4.1, 10.6; 12.3; Atlas; Interactive Atlas	Much of the near-term information and comparison to historical observations allows us to quantify the climate adaptation challenges for the next decades as well as the opportunities to reduce climate change by pursuing lower emissions. For this timescale both the forced changes and the internal variability are important.
How can the climate benefit of mitigating emissions of different greenhouse gases be compared?	7.6	For mitigation challenges, it is important to compare efforts to reduce emissions of CO_2 versus emissions of other climate forcers, such as, short-lived CH_4 or long-lived N_2O. Global Warming Potentials (GWPs), which are used in the UNFCCC and in emission inventories, are updated and various other metrics are also investigated. While the NDCs of Parties to the PA, emission inventories under the UNFCCC, and various emission trading schemes work on the basis of GWP-weighted emissions, some recent discussion in the scientific literature also considers projecting temperatures induced by short-lived climate forcers on the basis of emission changes, not emissions per se.
Do mountain glaciers shrink currently and in the near-future in regions that are currently dependent on this seasonal freshwater supply?	2.3.2.3; 9.5; Cross-chapter Box 10.4; 12.4: 8.4.1; Atlas.5.2.2; Atlas.5.3.2; Atlas.6.2; Atlas.9.2	Mountain glaciers and seasonal snow cover often feed downstream river systems during the melting period, and can be an important source of freshwater. Changing river discharge can pose adaptation challenges. Melting mountain glaciers are among the main contributors to observed global mean sea level rise.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

What are the capacities and limitations in the provision of regional climate information for adaptation and risk management?	10.5;10.6; Box 10.2; Cross-Chapter Box 10.4; 11.9; Cross-Chapter Box 1.3; 12.6; Cross-Chapter Box 12.1	Challenges for adaptation and risk management are predominantly local, even if globally interlinked. There are a number of approaches used in the production of regional climate information for adaptation purposes focusing on regional scales. All of them consider a range of sources of data and knowledge that are distilled into, at times contextual, climate information. A wealth of examples can be found in this Report, including assessments of extremes and climatic impact-drivers, and attribution at regional scales. Specific regions and case studies for regional projections are considered, like the Sahel and West African monsoon drought and recovery, the Southern Australian rainfall decline, the Caribbean small island summer drought, and regional projections are discussed for Cape Town, the Mediterranean region and Hindu Kush Himalaya.
How important are reductions in short-lived climate forcers compared to the reduction of CO_2 and other long-lived greenhouse gases?	6.1; 6.6; 6.7; 7.6	While most of the radiative forcing which causes climate change comes from CO_2 emissions, short-lived climate forcers also play an important role in the anthropogenic effect on climate change. Many aerosol species, especially SO_4, tend to cool the climate and their reduction leads to a masking of greenhouse gas induced warming. On the other hand, many short-lived species themselves exert a warming effect, including black carbon and CH_4, the second most important anthropogenic greenhouse gas (in terms of current radiative forcing). Notably, the climate response to aerosol emissions has a strong regional pattern and is different from that of greenhouse gas driven warming.
What are potential co-benefits and side-effects of climate change mitigation?	5.6.2; 6.1; 6.7.5	The reduction of fossil-fuel-related emissions often goes hand-in-hand with a reduction of air pollutants, such as aerosols and ozone. Reductions will improve air quality and result in broader environmental benefits (reduced acidification, eutrophication, and often tropospheric ozone recovery). More broadly, various co-benefits are discussed in WGII and WGIII, as well as co-benefits and side-effects related to certain mitigation actions, like increased biomass use and associated challenges to food security and biodiversity conservation.
What large near-term surprises could result in particular adaptation challenges?	1.4; 4.4.4; Cross-Chapter Box 4.1; 8.5.2; 11.2.4; Cross-	Surprises can come from a range of sources: from incomplete understanding of the climate system, from surprises in emissions of natural (e.g., volcanic) sources, or from disruptions to the carbon cycle associated with a warming climate (e.g., methane release from permafrost thawing, tropical forest dieback). There could be large natural variability in the near-term; or also accelerated climate

ACCEPTED VERSION SUBJECT TO FINAL EDITS

	Chapter Box 12.1	change due to a markedly more sensitive climate than previously thought. When the next large explosive volcanic eruption will happen is unknown. The largest volcanic eruptions over the last few hundred years led to substantial but temporary cooling, including precipitation changes.

[END CROSS-CHAPTER BOX 1.1, TABLE 1 HERE]

[END CROSS-CHAPTER BOX 1.1 HERE]

Sustainable Development Goals (SDGs). Many interactions among environmental problems and development are addressed in the United Nations 2030 Agenda for Sustainable Development and its Sustainable Development Goals. The 2030 Agenda, supported by the finance-oriented Addis Ababa Action Agenda (UN DESA, 2015), calls on nations to 'take the bold and transformative steps which are urgently needed to shift the world onto a sustainable and resilient path.' The 2030 Agenda recognizes that 'climate change is one of the greatest challenges of our time and its adverse impacts undermine the ability of all countries to achieve sustainable development.' SDG 13 deals explicitly with climate change, establishing several targets for adaptation, awareness-raising and finance. Climate and climate change are also highly relevant to most other SDGs, while acknowledging UNFCCC as the main forum to negotiate the global response to climate change. For example, both long-lived greenhouse gases (LLGHGs), through mitigation decisions, and SLCFs, through air quality, are relevant to SDG 11 (sustainable cities and communities). Chapter 6 assesses SLCF effects on climate and the implications of changing climate for air quality, including opportunities for mitigation relevant to the SDGs (Chapter 6, Box 6.2). Also, the UN Conference on Housing and Sustainable Development established a New Urban Agenda (United Nations, 2017) envisaging cities as part of the solutions for sustainable development, climate change adaptation and mitigation.

The Sendai Framework for Disaster Risk Reduction (SFDRR). The Sendai Framework for Disaster Risk Reduction is a non-binding agreement to reduce risks associated with disasters of all scales, frequencies and onset rates caused by natural or human-made hazards, including climate change. The SFDRR outlines targets and priorities for action including 'Understanding disaster risk', along the dimensions of vulnerability, exposure of persons and assets and hazard characteristics. Chapter 12 assesses climate information relevant to regional impact and risk assessment with a focus on climate hazards and other aspects of climate that influence society and ecosystem and makes the link with Working Group II. AR6 adopts a consistent risk and solution-oriented framing (Cross-Chapter Box 1.3) that calls for a multidisciplinary approach and cross-working group coordination in order to ensure integrative discussions of major scientific issues associated with integrative risk management and sustainable solutions (IPCC, 2017).

The Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES). Efforts to address climate change take place alongside and in the context of other major environmental problems, such as biodiversity loss. The Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES), established in 2012, builds on the IPCC model of a science-policy interface and assessment. The Platform's objective is to 'strengthen the science-policy interface for biodiversity and ecosystem services for the conservation and sustainable use of biodiversity, long-term human well-being and sustainable development' (UNEP, 2012). SROCC (IPCC, 2019b) and SRCCL (IPCC, 2019a) assessed the relations between changes in biodiversity and in the climate system. The rolling work programme of IPBES up to 2030 will address interlinkages among biodiversity, water, food and health. This assessment will use a nexus approach to examine interlinkages between biodiversity and the above-mentioned issues, including climate change mitigation and adaptation. Furthermore, IPBES and IPCC will directly collaborate on biodiversity and climate change under the rolling work programme.

Addressing climate change alongside other environmental problems, while simultaneously supporting

ACCEPTED VERSION SUBJECT TO FINAL EDITS

sustainable socioeconomic development, requires a holistic approach. Since AR5, there is increasing attention on the need for coordination among previously independent international agendas, recognizing that climate change, disaster risk, economic development, biodiversity conservation and human well-being are tightly interconnected. The current COVID-19 pandemic provides an example of the need for such interconnection, with its widespread impacts on economy, society and environment (e.g., Shan et al., 2020). Cross Chapter Box 6.1 in Chapter 6 assesses the consequences of the COVID-19 lockdowns on emissions of GHGs and SLCFs and related implications for the climate. Another example is the close link between SLCF emissions, climate evolution and air quality concerns (see Chapter 6). Emissions of halocarbons have previously been successfully regulated under the Montreal Protocol and its Kigali Amendment. This has been achieved in an effort to reduce ozone depletion that has also modulated anthropogenic climate influence (Estrada et al., 2013; Wu et al., 2013). In the process, emissions of some SLCFs are jointly regulated to reduce environmental and health impacts from air pollution (e.g., Gothenburg Protocol; Reis et al., 2012). Considering the recognized importance of SLCFs for climate, the IPCC decided in May 2019 to approve that the IPCC Task Force on National Greenhouse Gas Inventories produces an IPCC Methodology Report on SLCFs to develop guidance for national SLCFs inventories.

The evolving governance context since AR5 challenges the IPCC to provide policymakers and other actors with information relevant for both adaptation to and mitigation of climate change and for the loss and damage induced.

1.2.3 Linking science and society: communication, values, and the IPCC assessment process

This section assesses how the process of communicating climate information has evolved since AR5. It summarizes key issues regarding scientific uncertainty addressed in previous IPCC assessments and introduces the IPCC calibrated uncertainty language. Next it discusses the role of values in problem-driven, multidisciplinary science assessments such as this one. The section introduces climate services and how climate information can be tailored for greatest utility in specific contexts, such as the global stocktake. Finally, we briefly evaluate changes in media coverage of climate information since AR5, including the increasing role of internet sources and social media.

1.2.3.1 Climate change understanding, communication, and uncertainties

The response to climate change is facilitated when leaders, policymakers, resource managers, and their constituencies share basic understanding of the causes, effects, and possible future course of climate change (SR1.5, IPCC, 2018; SRCCL, IPCC, 2019a). Achieving shared understanding is complicated, since scientific knowledge interacts with pre-existing conceptions of weather and climate built up in diverse world cultures over centuries and often embedded in strongly held values and beliefs stemming from ethnic or national identities, traditions, religion, and lived relationships to weather, land and sea (Van Asselt and Rotmans, 1996; Rayner and Malone, 1998; Hulme, 2009, 2018; Green et al., 2010; Jasanoff, 2010; Orlove et al., 2010; Nakashima et al., 2012; Shepherd and Sobel, 2020). These diverse, more local understandings can both contrast with and enrich the planetary-scale analyses of global climate science (*high confidence*).

Political cultures also give rise to variation in how climate science knowledge is interpreted, used, and challenged (Leiserowitz, 2006; Oreskes and Conway, 2010; Brulle et al., 2012; Dunlap and Jacques, 2013; Mahony, 2014, 2015; Brulle, 2019). A meta-analysis of 87 studies carried out between 1998 and 2016 (62 USA national, 16 non-USA national, 9 cross-national) found that political orientation and political party identification were the second-most important predictors of views on climate change after environmental values (the strongest predictor) (McCright et al. 2016). Ruiz et al. (2020) systematically reviewed 34 studies of non-US nations or clusters of nations and 30 studies of the USA alone. They found that in the non-US studies, ‘changed weather’ and ‘socio-altruistic values’ were the most important drivers of public attitudes. For the USA case, by contrast, political affiliation and the influence of corporations were most important. Widely varying media treatment of climate issues also affects public responses (see Section 1.2.3.4). In summary, environmental and socio-altruistic values are the most significant influences on public opinion

ACCEPTED VERSION SUBJECT TO FINAL EDITS

about climate change globally, while political views, political party affiliation, and corporate influence also had strong effects, especially in the USA (*high confidence*).

Furthermore, climate change itself is not uniform. Some regions face steady, readily observable change, while others experience high variability that masks underlying trends (Section 1.4.1); most regions are subject to hazards, but some may also experience benefits, at least temporarily (see Chapters 11, 12, and Atlas). This non-uniformity may lead to wide variation in public climate change awareness and risk perceptions at multiple scales (Howe et al., 2015; Lee et al., 2015). For example, short-term temperature trends, such as cold spells or warm days, have been shown to influence public concern (Hamilton and Stampone, 2013; Zaval et al., 2014; Bohr, 2017).

Given these manifold influences and the highly varied contexts of climate change communication, special care is required when expressing findings and uncertainties, including IPCC assessments that inform decision making. Throughout the IPCC's history, all three Working Groups (WGs) have sought to explicitly assess and communicate scientific uncertainty (Le Treut et al., 2007; Cubasch et al., 2013). Over time, the IPCC has developed and revised a framework to treat uncertainties consistently across assessment cycles, reports, and Working Groups through the use of calibrated language (Moss and Schneider, 2000; IPCC, 2005). Since its First Assessment Report (IPCC, 1990a), the IPCC specified terms and methods for communicating authors' expert judgments (Mastrandrea and Mach, 2011). During the AR5 cycle, this calibrated uncertainty language was updated and unified across all WGs (Mastrandrea et al., 2010, 2011). Box 1.1 summarizes this framework as used in AR6.

[START BOX 1.1 HERE]

Box 1.1: Treatment of uncertainty and calibrated uncertainty language in AR6

The AR6 follows the approach developed for AR5 (Box 1.1, Figure 1), as described in the 'Guidance Notes for Lead Authors of the IPCC Fifth Assessment Report on Consistent Treatment of Uncertainties' (Mastrandrea et al., 2010). The uncertainty Guidance Note used in AR6 clarifies the relationship between the qualitative description of confidence and the quantitative representation of uncertainty expressed by the likelihood scale. The calibrated uncertainty language emphasizes traceability of the assessment throughout the process. Key chapter findings presented in the chapter Executive Summary are supported in the chapter text by a summary of the underlying literature that is assessed in terms of evidence and agreement, confidence, and also likelihood if applicable.

In all three WGs, author teams evaluate underlying scientific understanding and use two metrics to communicate the degree of certainty in key findings. These metrics are:

1. *Confidence:* a qualitative measure of the validity of a finding, based on the type, amount, quality and consistency of evidence (e.g., data, mechanistic understanding, theory, models, expert judgment) and the degree of agreement.
2. *Likelihood:* a quantitative measure of uncertainty in a finding, expressed probabilistically (e.g., based on statistical analysis of observations or model results, or both, and expert judgement by the author team or from a formal quantitative survey of expert views, or both).

Throughout IPCC reports, the calibrated language indicating a formal confidence assessment is clearly identified by *italics* (e.g., *medium confidence*). Where appropriate, findings can also be formulated as statements of fact without uncertainty qualifiers.

[START BOX 1.1, FIGURE 1 HERE]

Box 1.1, Figure 1: The IPCC AR6 approach for characterizing understanding and uncertainty in assessment findings. This diagram illustrates the step-by-step process authors use to evaluate and communicate the state

ACCEPTED VERSION SUBJECT TO FINAL EDITS

of knowledge in their assessment (Mastrandrea et al., 2010). Authors present evidence/agreement, confidence, or likelihood terms with assessment conclusions, communicating their expert judgments accordingly. Example conclusions drawn from this report are presented in the box at the bottom of the figure. [adapted from Mach et al. (2017)].

[END BOX 1.1, FIGURE 1 HERE]

Box.1.1, Figure 1 (adapted from Mach et al., 2017) shows the idealized step-by-step process by which IPCC authors assess scientific understanding and uncertainties. It starts with the evaluation of the available evidence and agreement (Steps 1–2). The following summary terms are used to describe the available evidence: *limited, medium,* or *robust*; and the degree of agreement: *low, medium,* or *high*. Generally, evidence is most robust when there are multiple, consistent, independent lines of high-quality evidence.

If the author team concludes that there is sufficient evidence and agreement, the level of confidence can be evaluated. In this step, assessments of evidence and agreement are combined into a single metric (Steps 3–5). The assessed level of confidence is expressed using five qualifiers: *very low, low, medium, high,* and *very high*. Step 4 depicts how summary statements for evidence and agreement relate to confidence levels. For a given evidence and agreement statement, different confidence levels can be assigned depending on the context, but increasing levels of evidence and degrees of agreement correlate with increasing confidence. When confidence in a finding is assessed to be *low*, this does not necessarily mean that confidence in its opposite is *high,* and vice versa. Similarly, *low confidence* does not imply distrust in the finding; instead, it means that the statement is the best conclusion based on currently available knowledge. Further research and methodological progress may change the level of confidence in any finding in future assessments.

If the expert judgement of the author team concludes that there is sufficient confidence and quantitative/probabilistic evidence, assessment conclusions can be expressed with likelihood statements (Box.1.1, Figure 1, Steps 5–6). Unless otherwise indicated, likelihood statements are related to findings for which the authors' assessment of confidence is '*high*' or '*very high*'. Terms used to indicate the assessed likelihood of an outcome include: *virtually certain*: 99–100% probability, *very likely*: 90–100%, *likely*: 66–100%, *about as likely as not*: 33–66%, *unlikely*: 0–33%, *very unlikely*: 0–10%, *exceptionally unlikely*: 0–1%. Additional terms (*extremely likely*: 95–100%, *more likely than not* >50–100%, and *extremely unlikely* 0–5%) may also be used when appropriate.

Likelihood can indicate probabilities for single events or broader outcomes. The probabilistic information may build from statistical or modelling analyses, other quantitative analyses, or expert elicitation. The framework encourages authors, where appropriate, to present probability more precisely than can be done with the likelihood scale, for example with complete probability distributions or percentile ranges, including quantification of tails of distributions important for risk management (Mach et al., 2017; see also Sections 1.2.2 and 1.4.4). In some instances, multiple combinations of confidence and likelihood are possible to characterize key findings. For example, a *very likely* statement might be made with *high confidence*, whereas a *likely* statement might be made with *very high confidence*. In these instances, the author teams consider which statement will convey the most balanced information to the reader.

Throughout this WGI report and unless stated otherwise, uncertainty is quantified using 90% uncertainty intervals. The 90% uncertainty interval, reported in square brackets [x to y], is estimated to have a 90% likelihood of covering the value that is being estimated. The range encompasses the median value and there is an estimated 10% combined likelihood of the value being below the lower end of the range (x) and above its upper end (y). Often the distribution will be considered symmetric about the corresponding best estimate (as in the illustrative example in the figure), but this is not always the case. In this report, an assessed 90% uncertainty interval is referred to as a '*very likely* range'. Similarly, an assessed 66% uncertainty interval is referred to as a '*likely* range'.

[END BOX 1.1 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Considerable critical attention has focused on whether applying the IPCC framework effectively achieves consistent treatment of uncertainties and clear communication of findings to users (Shapiro et al., 2010; Adler and Hirsch Hadorn, 2014). Specific concerns include, for example, the transparency and traceability of expert judgements underlying the assessment conclusions (Oppenheimer et al., 2016) and the context-dependent representations and interpretations of probability terms (Budescu et al., 2009, 2012; Janzwood, 2020). Budescu et al. (2014) surveyed 25 samples in 24 countries (a total of 10,792 individual responses), finding that even when shown IPCC uncertainty guidance, lay readers systematically misunderstood IPCC likelihood statements. When presented with a 'high likelihood' statement, they understood it as indicating a lower likelihood than intended by the IPCC authors. Conversely, they interpreted 'low likelihood' statements as indicating a higher likelihood than intended. In another study, British lay readers interpreted uncertainty language somewhat differently from IPCC guidance, but Chinese lay people reading the same uncertainty language translated into Chinese differed much more in their interpretations (Harris et al., 2013). Further, even though it is objectively more probable that wide uncertainty intervals will encompass true values, wide intervals were interpreted by lay people as implying subjective uncertainty or lack of knowledge on the part of scientists (Løhre et al., 2019). Mach et al. (2017) investigated the advances and challenges in approaches to expert judgment in the AR5. Their analysis showed that the shared framework increased the overall comparability of assessment conclusions across all WGs and topics related to climate change, from the physical science basis to resulting impacts, risks, and options for response. Nevertheless, many challenges in developing and communicating assessment conclusions persist, especially for findings drawn from multiple disciplines and Working Groups, for subjective aspects of judgments, and for findings with substantial uncertainties (Adler and Hirsch Hadorn, 2014). In summary, the calibrated language cannot entirely prevent misunderstandings, including a tendency to systematically underestimate the probability of the IPCC's higher-likelihood conclusions and overestimate the probability of the lower-likelihood ones (*high confidence*), however a consistent and systematic approach across Working Groups to communicate the assessment outcomes is an important characteristic of the IPCC.

Some suggested alternatives are impractical, such as always including numerical values along with calibrated language (Budescu et al., 2014). Others, such as using positive instead of negative expressions of low to medium probabilities, show promise but were not proposed in time for adoption in AR6 (Juanchich et al., 2020). This report therefore retains the same calibrated language used in AR5 (Box 1.1). Like previous reports, AR6 also includes FAQs that express its chief conclusions in plain language designed for lay readers.

The framework for communicating uncertainties does not address when "deep uncertainty" is identified in the assessment (Adler and Hirsch Hadorn, 2014). The definition of deep uncertainty in IPCC assessments has been described in the context of the SROCC (IPCC, 2019b; Box 5 in Abram et al. (2019)). A situation of deep uncertainty exists when experts or stakeholders do not know or cannot agree on: (1) appropriate conceptual models that describe relationships among key driving forces in a system; (2) the probability distributions used to represent uncertainty about key variables and parameters; and/or (3) how to weigh and value desirable alternative outcomes (Abram et al., 2019). (See also Cross-Chapter Box 1.2, Annex VII Glossary) Since AR5, the 'storylines' or 'narratives' approach has been used to address issues related to deep uncertainty, for example low-likelihood events that would have high impact if they occurred, to better inform risk assessment and decision making (see Section 1.4.4). Chapter 9 (Section 9.2.3) notes deep uncertainty in long term projections for sea level rise, and in processes related to Marine Ice Sheet Instability and Marine Ice Cliff Instability.

1.2.3.2 Values, science, and climate change communication

As noted above, values — fundamental attitudes about what is important, good, and right — play critical roles in all human endeavours, including climate science. In AR5, Chapters 3 and 4 of the WGIII assessment addressed the role of cultural, social, and ethical values in climate change mitigation and sustainable development (Fleurbaey et al., 2014; Kolstad et al., 2014). These values include widely accepted concepts of human rights, enshrined in international law, that are relevant to climate impacts and policy objectives (Hall

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and Weiss, 2012; Peel and Osofsky, 2018; Setzer and Vanhala, 2019). Specific values – human life, subsistence, stability, and equitable distribution of the costs and benefits of climate impacts and policies – are explicit in the texts of the UNFCCC and the PA (Breakey et al., 2016; Dooley and Parihar, 2016). Here we address the role of values in how scientific knowledge is created, verified, and communicated. Chapters 10, 12, and Cross-Chapter Box 12.2 address how the specific values and contexts of users can be addressed in the co-production of climate information.

The epistemic (knowledge-related) values of science include explanatory power, predictive accuracy, falsifiability, replicability, and justification of claims by explicit reasoning (Popper, 1959; Kuhn, 1977). These are supported by key institutional values, including openness, 'organized scepticism,' and objectivity or 'disinterestedness' (Merton, 1973), operationalized as well-defined methods, documented evidence, publication, peer review, and systems for institutional review of research ethics (COSEPUP, 2009). In recent decades, open data, open code, and scientific cyberinfrastructure (notably the Earth System Grid Federation, a partnership of climate modeling centers dedicated to supporting climate research by providing secure, web-based, distributed access to climate model data) have facilitated scrutiny from a larger range of participants, and FAIR data stewardship principles – making data Findable, Accessible, Interoperable and Reusable (FAIR) – are being mainstreamed in many fields (Wilkinson et al., 2016). Climate science norms and practices embodying these scientific values and principles include the publication of data and model code, multiple groups independently analysing the same problems and data, model intercomparison projects (MIPs), explicit evaluations of uncertainty, and comprehensive assessments by national academies of science and the IPCC.

The formal Principles Governing IPCC Work (1998, amended 2003, 2006, 2012, 2013) specify that assessments should be 'comprehensive, objective, open and transparent.' The IPCC assessment process seeks to achieve these goals in several ways: by evaluating evidence and agreement across all relevant peer-reviewed literature, especially that published or accepted since the previous assessment; by maintaining a traceable, transparent process that documents the reasoning, data, and tools used in the assessment; and by maximizing the diversity of participants, authors, experts, reviewers, institutions, and communities represented, across scientific discipline, geographical location, gender, ethnicity, nationality, and other characteristics. The multi-stage review process is critical to ensure an objective, comprehensive and robust assessment, with hundreds of scientists, other experts, and governments providing comments to a series of drafts before the report is finalised.

Social values are implicit in many choices made during the construction, assessment, and communication of climate science information (Heymann et al., 2017; Skelton et al., 2017). Some climate science questions are prioritised for investigation, or given a specific framing or context, because of their relevance to climate policy and governance. One example is the question of how the effects of a 1.5°C global warming would differ from those of a 2°C warming, an assessment specifically requested by Parties to the PA. SR1.5 (2018) explicitly addressed this issue 'within the context of sustainable development; considerations of ethics, equity and human rights; and the problem of poverty' (Chapters 1 and 5; see also Hoegh-Guldberg et al., 2019) following the outcome of the approval of the outline of the Special Report by the IPCC during its 44th Session (Bangkok, Thailand, 17-20 October 2016). Likewise, particular metrics are sometimes prioritized in climate model improvement efforts because of their practical relevance for specific economic sectors or stakeholders. Examples include reliable simulation of precipitation in a specific region, or attribution of particular extreme weather events to inform rebuilding and future policy (see Chapters 8 and 11; Intemann, 2015; Otto et al., 2018; James et al., 2019). Sectors or groups whose interests do not influence research and modelling priorities may thus receive less information in support of their climate-related decisions (Parker and Winsberg, 2018).

Recent work also recognizes that choices made throughout the research process can affect the relative likelihood of false alarms (overestimating the probability and/or magnitude of hazards) or missed warnings (underestimating the probability and/or magnitude of hazards), known respectively as Type I and Type II errors. Researchers may choose different methods depending on which type of error they view as most important to avoid, a choice that may reflect social values (Douglas, 2009; Knutti, 2018; Lloyd and Oreskes, 2018). This reflects a fundamental trade-off between the values of reliability and informativeness. When

ACCEPTED VERSION SUBJECT TO FINAL EDITS

uncertainty is large, researchers may choose to report a wide range as '*very likely*', even though it is less informative about potential consequences. By contrast, high-likelihood statements about a narrower range may be more informative, yet also prove less reliable if new evidence later emerges that widens the range. Furthermore, the difference between narrower and wider uncertainty intervals has been shown to be confusing to lay readers, who often interpret wider intervals as less certain (Løhre et al., 2019).

1.2.3.3 Climate information, co-production, and climate services

In AR6, 'climate information' refers to specific information about the past, current, or future state of the climate system that is relevant for mitigation, adaptation and risk management. Cross-Chapter Box 1.1 is an example of climate information at the global scale. It provides climate change information potentially relevant to the global stocktake, and indicates where in AR6 this information may be found.

Responding to national and regional policymakers' needs for tailored information relevant to risk assessment and adaptation, AR6 emphasizes assessment of regional information more than earlier reports. Here the phrase 'regional climate information' refers to predefined reference sets of land and ocean regions; various typological domains (such as mountains or monsoons); temporal frames including baseline periods as well as near-term (2021–2040), medium-term (2041–2060), and long-term (2081–2100); and global warming levels (Sections 1.4.1 and 1.4.5; Chapters 10, 12, and Atlas). Regional climate change information is constructed from multiple lines of evidence including observations, paleoclimate proxies, reanalyses, attribution of changes and climate model projections from both global and regional climate models (Section 1.5.3, Chapter 10, Section 10.2 to 10.4). The constructed regional information needs to take account of user context and values for risk assessment, adaptation and policy decisions (Section 1.2.3, Chapter 10, Section 10.5).

As detailed in Chapter 10, scientific climate information often requires 'tailoring' to meet the requirements of specific decision-making contexts. In a study of the UK Climate Projections 2009 project, researchers concluded that climate scientists struggled to grasp and respond to users' information needs because they lacked experience interacting with users, institutions, and scientific idioms outside the climate science domain (Porter and Dessai, 2017). Economic theory predicts the value of 'polycentric' approaches to climate change informed by specific global, regional, and local knowledge and experience (Ostrom, 1996, 2012). This is confirmed by numerous case studies of extended, iterative dialogue among scientists, policymakers, resource managers, and other stakeholders to produce mutually understandable, usable, task-related information and knowledge, policymaking and resource management around the world (Lemos and Morehouse, 2005; Lemos et al., 2012, 2014, 2018; see Vaughan and Dessai, 2014 for a critical view). SR1.5 (2018) assessed that 'education, information, and community approaches, including those that are informed by indigenous knowledge and local knowledge, can accelerate the wide-scale behaviour changes consistent with adapting to and limiting global warming to 1.5°C. These approaches are more effective when combined with other policies and tailored to the motivations, capabilities and resources of specific actors and contexts (*high confidence*).' These extended dialogic 'co-production' and education processes have thus been demonstrated to improve the quality of both scientific information and governance (*high confidence*) (Chapter 10, Section 10.5; Cross Chapter Box 12.2 in Chapter 12).

Since AR5, 'climate services' have increased at multiple levels (local, national, regional, and global) to aid decision-making of individuals and organizations and to enable preparedness and early climate change action. These services include appropriate engagement from users and providers, are based on scientifically credible information and producer and user expertise, have an effective access mechanism, and respond to the users' needs (Hewitt et al., 2012; Annex VII Glossary). A Global Framework for Climate Services (GFCS) was established in 2009 by the World Meteorological Organization (WMO) in support of these efforts (Hewitt et al., 2012; Lúcio and Grasso, 2016). Climate services are provided across sectors and timescales, from sub-seasonal to multi-decadal and support co-design and co-production processes that involve climate information providers, resource managers, planners, practitioners and decision makers (Brasseur and Gallardo, 2016; Trenberth et al., 2016; Hewitt et al., 2017). For example, they may provide high-quality data on temperature, rainfall, wind, soil moisture and ocean conditions, as well as maps, risk and vulnerability analyses, assessments, and future projections and scenarios. These data and information

ACCEPTED VERSION SUBJECT TO FINAL EDITS

products may be combined with non-meteorological data, such as agricultural production, health trends, population distributions in high-risk areas, road and infrastructure maps for the delivery of goods, and other socio-economic variables, depending on users' needs (WMO, 2020a). Cross-chapter Box 12.2 in Chapter 12 illustrates the diversity of climate services with three examples from very different contexts.

The current landscape of climate services is assessed in detail in Chapter 12 (Section 12.6), with a focus on multi-decadal timescales relevant for climate change risk assessment. Other information relevant to improving climate services for decision making includes the assessment of methods to construct regional information (Chapter 10), as well as projections at the regional level (Atlas) relevant for impact and risk assessment in different sectors (Chapter 12).

1.2.3.4 Media coverage of climate change

Climate services focus on users with specific needs for climate information, but most people learn about climate science findings from media coverage. Since AR5, research has expanded on how mass media report climate change and how their audiences respond (Dewulf, 2013; Jaspal and Nerlich, 2014; Jaspal et al., 2014). For example, in five European Union (EU) countries, television coverage of the AR5 used 'disaster' and 'opportunity' as its principal themes, but virtually ignored the 'risk' framing introduced by AR5 WGII (Painter, 2015) and now extended by the AR6 (see Cross-Chapter Box 1.3). Other studies show that people react differently to climate change news when it is framed as a catastrophe (Hine et al., 2015), as associated with local identities (Sapiains et al., 2016), or as a social justice issue (Howell, 2013). Similarly, audience segmentation studies show that responses to climate change vary between groups of people with different, although not necessarily opposed, views on this phenomenon (e.g., Maibach et al., 2011; Sherley et al., 2014; Detenber et al., 2016). In Brazil, two studies have shown the influence of mass media on the high level of public climate change concern in that country (Rodas and DiGiulio, 2017; Dayrell, 2019). In the USA, analyses of television network news show that climate change receives minimal attention, is most often framed in a political context, and largely fails to link extreme weather events to climate change using appropriate probability framing (Hassol et al., 2016). However, recent evidence suggests that Climate Matters (an Internet resource for US TV weathercasters to link weather to climate change trends) may have had a positive effect on public understanding of climate change (Myers et al., 2020). Also, some media outlets have recently adopted and promoted terms and phrases stronger than the more neutral 'climate change' and 'global warming', including 'climate crisis', 'global heating', and 'climate emergency' (Zeldin-O'Neill, 2019). Google searches on those terms, and on 'climate action,' increased 20-fold in 2019, when large social movements such as the School Strikes for Climate gained worldwide attention (Thackeray et al., 2020). We thus assess that specific characteristics of media coverage play a major role in climate understanding and perception (*high confidence*), including how IPCC assessments are received by the general public.

Since AR5, social media platforms have dramatically altered the mass-media landscape, bringing about a shift from uni-directional transfer of information and ideas to more fluid, multi-directional flows (Pearce et al., 2019). A survey covering 18 Latin American countries (StatKnows-CR2, 2019) found that the main sources of information about climate change mentioned were the Internet (52% of mentions), followed by social media (18%). There are well-known challenges with social media, such as misleading or false presentations of scientific findings, incivility that diminishes the quality of discussion around climate change topics, and 'filter bubbles' that restrict interactions to those with broadly similar views (Anderson and Huntington, 2017). However, at certain moments (such as at the release of the AR5 WGI report), Twitter studies have found that more mixed, highly-connected groups existed, within which members were less polarized (Pearce et al., 2014; Williams et al., 2015). Thus, social media platforms may in some circumstances support dialogic or co-production approaches to climate communication. Because the contents of IPCC reports speak not only to policymakers, but also to the broader public, the character and effects of media coverage are important considerations across Working Groups.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

1.3 How we got here: the scientific context

Scientific understanding of the climate system's fundamental features is robust and well established. This section briefly presents the major lines of evidence in climate science (Figure 1.6). It illustrates their long history and summarises key findings from the WGI contribution to AR5, where relevant referencing previous IPCC assessments for comparison. Box 1.2 summarises major findings from three Special Reports already released during the sixth IPCC assessment cycle. This chapter's Appendix 1A summarises the principal findings of all six IPCC WGI Assessment Reports, including the present one, in a single table for ready reference.

[START FIGURE 1.6 HERE]

Figure 1.6: Climate science milestones, between 1817-2021. Milestones in observations (top); Curves of global surface air temperature (GMST) using HadCRUT5 (Morice et al., 2021) and atmospheric CO_2 concentrations from Antarctic ice cores (Lüthi et al., 2008; Bereiter et al., 2015) and direct air measurements from 1957 onwards (Tans and Keeling, 2020) (see Figure 1.4 for details) (middle). Milestone in scientific understanding of the CO2 enhanced greenhouse effect (bottom). Further details on each milestone are available in Chapter 1, Section 1.3, and Chapter 1 of AR4.

[END FIGURE 1.6 HERE]

1.3.1 Lines of evidence: instrumental observations

Instrumental observations of the atmosphere, ocean, land, biosphere, and cryosphere underpin all understanding of the climate system. This section describes the evolution of instrumental data for major climate variables at Earth's land and ocean surfaces, at altitude in the atmosphere, and at depth in the ocean. Many data records exist, of varying length, continuity, and spatial distribution; Figure 1.7 gives a schematic overview of temporal coverage.

Instrumental weather observation at the Earth's surface dates to the invention of thermometers and barometers in the 1600s. National and colonial weather services built networks of surface stations in the 1800s. By the mid-19th century, semi-standardized naval weather logs recorded winds, currents, precipitation, air pressure, and temperature at sea, initiating the longest continuous quasi-global instrumental record (Maury, 1849, 1855, 1860). Because the ocean covers over 70% of global surface area and constantly exchange energy with the atmosphere, both air and sea surface temperatures (SST) recorded in these naval logs are crucial variables in climate studies. Dove (1853) mapped seasonal isotherms over most of the globe. By 1900, a patchy weather data-sharing system reached all continents except Antarctica. Regular compilation of climatological data for the world began in 1905 with the Réseau Mondial (Meteorological Office and Shaw, 1920), and the similar compilations World Weather Records (Clayton, 1927) and Monthly Climatic Data for the World (est. 1948) have been published continuously since their founding.

Land and ocean surface temperature data have been repeatedly evaluated, refined, and extended (Section 1.5.1). As computer power increased and older data were recovered from handwritten records, the number of surface station records used in published global land temperature time series grew. A pioneering study for 1880–1935 used fewer than 150 stations (Callendar, 1938). A benchmark study of 1880–2005 incorporated 4300 stations (Brohan et al., 2006). A study of the 1753–2011 period included previously unused station data, for a total of 36,000 stations (Rohde et al., 2013); recent versions of this dataset comprise over 40,000 land stations (Rohde and Hausfather, 2020). Several centres, including NOAA, Hadley, and Japan Meteorological Agency (JMA), each produce SST datasets independently calculated from instrumental records. In the 2000s, adjustments for bias due to different measurement methods (buckets, engine intake thermometers, moored and drifting buoys) resulted in major improvements of SST data (Thompson et al., 2008), and these improvements continue (Huang et al., 2017; Kennedy et al., 2019). SST and land-based data are incorporated into global surface temperature datasets calculated independently by multiple research

ACCEPTED VERSION SUBJECT TO FINAL EDITS

groups, including NOAA, NASA, Berkeley Earth, Hadley-CRU, JMA, and China Meteorological Administration (CMA). Each group aggregates the raw measurement data, applies various adjustments for non-climatic biases such as urban heat-island effects, and addresses unevenness in geospatial and temporal sampling with various techniques (see Chapter 2, Section 2.3.1.1.3 and Table 2.4 for references). Other research groups provide alternative interpolations of these datasets using different methods (e.g., Cowtan and Way, 2014; Kadow et al., 2020). Using the then available global surface temperature datasets, WGI AR5 assessed that the global mean surface temperature (GMST) increased by 0.85°C from 1880 to 2012 and found that each of the three decades following 1980 was successively warmer at the Earth's surface than any preceding decade since 1850 (IPCC, 2013b). Marine air temperatures, especially those measured during night-time, are increasingly also used to examine variability and long-term trends (e.g., Rayner et al., 2006; Kent et al., 2013; Cornes et al., 2020; Junod and Christy, 2020). Cross-Chapter Box 2.3 in Chapter 2 discusses updates to the global temperature datasets, provides revised estimates for the observed changes and considers whether marine air temperatures are changing at the same rate as SSTs.

Data at altitude came initially from scattered mountain summits, balloons, and kites, but the upper troposphere and stratosphere were not systematically observed until radiosonde (weather balloon) networks emerged in the 1940s and 1950s. These provide the longest continuous quasi-global record of the atmosphere's vertical dimension (Stickler et al., 2010). New methods for spatial and temporal homogenisation (intercalibration and quality control) of radiosonde records were introduced in the 2000s (Sherwood et al., 2008, 2015; Haimberger et al., 2012). Since 1978, Microwave Sounding Units (MSU) mounted on Earth-orbiting satellites have provided a second high-altitude data source, measuring temperature, humidity, ozone, and liquid water throughout the atmosphere. Over time, these satellite data have required numerous adjustments to account for such factors as orbital precession and decay (Edwards, 2010). Despite repeated adjustments, however, marked differences remain in the temperature trends from surface, radiosonde, and satellite observations; between the results from three research groups that analyse satellite data (UAH, RSS, and NOAA); and between modelled and satellite-derived tropospheric warming trends (Thorne et al., 2011; Santer et al., 2017). These differences are the subject of ongoing research (Maycock et al., 2018). In the 2000s, Atmospheric Infrared Sounder (AIRS) and radio occultation (GNSS-RO) measurements provided new ways to measure temperature at altitude, complementing data from the MSU. GNSS-RO is a new independent, absolutely calibrated source, using the refraction of radio-frequency signals from the Global Navigation Satellite System (GNSS) to measure temperature, pressure, and water vapour (Chapter 2, Section 2.3.1.2.1; Foelsche et al., 2008; Anthes, 2011).

Heat-retaining properties of the atmosphere's constituent gases were closely investigated in the 19th century. Foote, (1856) measured solar heating of CO_2 experimentally and argued that higher concentrations in the atmosphere would increase Earth's temperature. Water vapour, ozone, carbon dioxide, and certain hydrocarbons were found to absorb longwave (infrared) radiation, the principal mechanism of the greenhouse effect (Tyndall, 1861). 19th-century investigators also established the existence of a natural biogeochemical carbon cycle. CO_2 emitted by volcanoes is removed from the atmosphere through a combination of silicate rock weathering, deep-sea sedimentation, oceanic absorption, and biological storage in plants, shellfish, and other organisms. On multi-million-year timescales, the compression of fossil organic matter stores carbon as coal, oil, and natural gas (Chamberlin, 1897, 1898; Ekholm, 1901).

Arrhenius (1896) calculated that a doubling of atmospheric carbon dioxide would produce a 5–6°C warming, but in 1900 new measurements seemed to rule out CO_2 as a greenhouse gas due to overlap with the absorption bands of water vapour (Ångström, 1900; Very and Abbe, 1901). Further investigation and more sensitive instruments later overturned Ångström's conclusion (Fowle, 1917; Callendar, 1938). Nonetheless, the major role of CO_2 in the energy balance of the atmosphere was not widely accepted until the 1950s (Callendar, 1949; Plass, 1956, 1961; Manabe and Möller, 1961; Weart, 2008; Edwards, 2010). Revelle and Keeling established carbon dioxide monitoring stations in Antarctica and Hawaii during the 1957–1958 International Geophysical Year (Revelle and Suess, 1957; Keeling, 1960). These stations have tracked rising atmospheric CO_2 concentrations from 315 ppm in 1958 to 414 ppm in 2020. Ground-based monitoring of other greenhouse gases followed. The Greenhouse Gases Observing Satellite (GOSat) was launched in 2009, and two Orbiting Carbon Observatory satellite instruments have been in orbit since 2014.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

WGI AR5 highlighted 'the other CO_2 problem' (Doney et al., 2009), that is, ocean acidification caused by the absorption of some 20–30% of anthropogenic carbon dioxide from the atmosphere and its conversion to carbonic acid in seawater. WGI AR5 assessed that the pH of ocean surface water has decreased by 0.1 since the beginning of the industrial era (*high confidence*), indicating approximately a 30% increase in acidity (IPCC, 2013b).

With a heat capacity about 1000 times greater than that of the atmosphere, Earth's ocean stores the vast majority of energy retained by the planet. Ocean currents transport the stored heat around the globe and, over decades to centuries, from the surface to its greatest depths. The ocean's thermal inertia moderates faster changes in radiative forcing on land and in the atmosphere, reaching full equilibrium with the atmosphere only after hundreds to thousands of years (Yang and Zhu, 2011). The earliest subsurface measurements in the open ocean date to the 1770s (Abraham et al., 2013). From 1872–76, the research ship *HMS Challenger* measured global ocean temperature profiles at depths up to 1700 m along its cruise track. By 1900, research ships were deploying instruments such as Nansen bottles and Mechanical BathyThermographs (MBTs) to develop profiles of the upper 150 m in areas of interest to navies and commercial shipping (Abraham et al., 2013). Starting in 1967, eXpendable BathyThermographs (XBTs) were deployed by scientific and commercial ships along repeated transects to measure temperature to 700 m (Goni et al., 2019). Ocean data collection expanded in the 1980s with the Tropical Ocean Global Experiment (TOGA; Gould, 2003). Marine surface observations for the globe, assembled in the mid-1980s in the International Comprehensive Ocean-Atmosphere Data Set (ICOADS; Woodruff et al., 1987, 2005), were extended to 1662–2014 using newly recovered marine records and metadata (Woodruff et al., 1998; Freeman et al., 2017). The Argo submersible float network developed in the early 2000s provided the first systematic global measurements of the 700–2000 m layer. Comparing the *HMS Challenger* data to data from Argo submersible floats revealed global subsurface ocean warming on the centennial scale (Roemmich et al., 2012). WGI AR5 assessed with *high confidence* that ocean warming accounted for more than 90% of the additional energy accumulated by the climate system between 1971 and 2010 (IPCC, 2013b). In comparison, warming of the atmosphere corresponds to only about 1% of the additional energy accumulated over that period (IPCC, 2013a). Chapter 2 summarises the ocean heat content datasets used in AR6 (Chapter 2, Section 2.3.3.1; Table 2.7).

Water expands as it warms. This thermal expansion, along with glacier mass loss, were the dominant contributors to global mean sea level rise during the 20th century (*high confidence*) according to AR5 (IPCC, 2013b). Sea level can be measured by averaging across tide gauges, some of which date to the 18th century. However, translating tide gauge readings into global mean sea levevl (GMSL) is challenging, since their spatial distribution is limited to continental coasts and islands, and their readings are relative to local coastal conditions that may shift vertically over time. Satellite radar altimetry, introduced operationally in the 1990s, complements the tide gauge record with geocentric measurements of GMSL at much greater spatial coverage (Katsaros and Brown, 1991; Fu et al., 1994). WGI AR5 assessed that global mean sea level rose by 0.19 [0.17 to 0.21] m over the period 1901–2010, and that the rate of sea level rise increased from 2.0 [1.7 to 2.3] mm yr^{-1} in 1971–2010 to 3.2 [2.8 to 3.6] mm yr^{-1} from 1993–2010. Warming of the ocean *very likely* contributed 0.8 [0.5 to 1.1] mm yr^{-1} of sea level change during 1971–2010, with the majority of that contribution coming from the upper 700 m (IPCC, 2013b). Chapter 2, Section 2.3.3.3 assesses current understanding of the extent and rate of sea level rise, past and present.

Satellite remote sensing also revolutionised studies of the cryosphere (Chapter 2, Section 2.3.2 and Chapter 9, Sections 9.3 to 9.5), particularly near the poles where conditions make surface observations very difficult. Satellite mapping and measurement of snow cover began in 1966, with land and sea ice observations following in the mid-1970s. Yet prior to the Third Assessment Repor, researchers lacked sufficient data to tell whether the Greenland and Antarctic Ice Sheets were shrinking or growing. Through a combination of satellite and airborne altimetry and gravity measurements, and improved knowledge of surface mass balance and perimeter fluxes, a consistent signal of ice loss for both ice sheets was established by the time of AR5 (Shepherd et al., 2012). After 2000, satellite radar interferometry revealed rapid changes in surface velocity at ice-sheet margins, often linked to reduction or loss of ice shelves (Scambos et al., 2004; Rignot and Kanagaratnam, 2006). Whereas sea ice area and concentration were continuously monitored since 1979 from microwave imagery, datasets for ice thickness emerged later from upward sonar profiling by submarines (Rothrock et al., 1999) and radar altimetry of sea-ice freeboards (Laxon et al., 2003). A recent reconstruction

ACCEPTED VERSION SUBJECT TO FINAL EDITS

of Arctic sea ice extent back to 1850 found no historical precedent for the Arctic sea ice minima of the 21st century (Walsh et al., 2017). Glacier length has been monitored for decades to centuries; internationally coordinated activities now compile worldwide glacier length and mass balance observations (World Glacier Monitoring Service, Zemp et al., 2015), global glacier outlines (Randolph Glacier Inventory, Pfeffer et al., 2014), and ice thickness of about 1100 glaciers (GlaThiDa, Gärtner-Roer et al., 2014). In summary, these data allowed WGI AR5 to assess that over the last two decades, the Greenland and Antarctic Ice Sheets have been losing mass, glaciers have continued to shrink almost worldwide, and Arctic sea ice and Northern Hemisphere spring snow cover have continued to decrease in extent (*high confidence*) (IPCC, 2013b).

1.3.2 Lines of evidence: paleoclimate

With the gradual acceptance of geological 'deep time' in the 19th century came investigation of fossils, geological strata, and other evidence pointing to large shifts in the Earth's climate, from ice ages to much warmer periods, across thousands to billions of years. This awareness set off a search for the causes of climatic changes. The long-term perspective provided by paleoclimate studies is essential to understanding the causes and consequences of natural variations in climate, as well as crucial context for recent anthropogenic climatic change. The reconstruction of climate variability and change over recent millennia began in the 1800s (Brückner et al., 2000; Brückner, 2018 [1890]; Coen, 2018, 2020). In brief, paleoclimatology reveals the key role of carbon dioxide and other greenhouse gases in past climatic variability and change, the magnitude of recent climate change in comparison to past glacial-interglacial cycles, and the unusualness recent climate change (Section 1.2.1.2; Cross Chapter Box 2.1 in Chapter 2; Tierney et al., 2020). FAQ 1.3 provides a plain-language summary of its importance.

Paleoclimate studies reconstruct the evolution of Earth's climate over hundreds to billions of years using pre-instrumental historical archives, indigenous knowledge and natural archives left behind by geological, chemical, and biological processes (Figure 1.7). Paleoclimatology covers a wide range of temporal scales, ranging from the human historical past (decades to millennia) to geological deep time (millions to billions of years). Paleoclimate reference periods are presented in Cross Chapter Box 2.1 in Chapter 2.

Historical climatology aids near-term paleoclimate reconstructions using media such as diaries, almanacs, and merchant accounts that describe climate-related events such as frosts, thaws, flowering dates, harvests, crop prices, and droughts (Lamb, 1965, 1995; Le Roy Ladurie, 1967; Brázdil et al., 2005). Meticulous records by Chinese scholars and government workers, for example, have permitted detailed reconstructions of China's climate back to 1000 CE, and even beyond (Louie and Liu, 2003; Ge et al., 2008). Climatic phenomena such as large-scale, regionally and temporally distributed warmer and cooler periods of the past 2000 years were originally reconstructed from European historical records (Lamb, 1965, 1995; Le Roy Ladurie, 1967; Neukom et al., 2019).

Indigenous and local knowledge have played an increasing role in historical climatology, especially in areas where instrumental observations are sparse. Peruvian fishermen named the periodic El Niño warm current in the Pacific, linked by later researchers to the Southern Oscillation (Cushman, 2004). Inuit communities have contributed to climatic history and community based monitoring across the Arctic (Riedlinger and Berkes, 2001; Gearheard et al., 2010). Indigenous Australian knowledge of climatic patterns has been offered as a complement to sparse observational records (Green et al., 2010; Head et al., 2014), such as those of sea-level

ACCEPTED VERSION SUBJECT TO FINAL EDITS

rise (Nunn and Reid, 2016). Ongoing research seeks to conduct further dialogue, utilise Indigenous and local knowledge as an independent line of evidence complementing scientific understanding, and analyse their utility for multiple purposes, especially adaptation (Laidler, 2006; Alexander et al., 2011; IPCC, 2019c). Indigenous and local knowledge are used most extensively by IPCC Working Group II.

Certain geological and biological materials preserve evidence of past climate changes. These 'natural archives' include corals, trees, glacier ice, speleothems (stalactites and stalagmites), loess deposits (dust sediments), fossil pollen, peat, lake sediment, and marine sediment (Stuiver, 1965; Eddy, 1976; Haug et al., 2001; Wang et al., 2001; Jones et al., 2009; Bradley, 2015). By the early 20th century, laboratory research had begun using tree rings to reconstruct precipitation and the possible influence of sunspots on climatic change (Douglass, 1914, 1919, 1922). Radiocarbon dating, developed in the 1940s (Arnold and Libby, 1949), allows accurate determination of the age of carbon-containing materials from the past 50,000 years; this dating technique ushered in an era of rapid progress in paleoclimate studies.

On longer timescales, tiny air bubbles trapped in polar ice sheets provide direct evidence of past atmospheric composition, including CO_2 levels (Petit et al., 1999), and the ^{18}O isotope in frozen precipitation serves as a proxy marker for temperature (Dansgaard, 1954). Sulphate deposits in glacier ice and as ash layers within sediment record major volcanic eruptions, providing another mechanism for dating. The first paleoclimate reconstructions used an almost 100,000-year ice core taken at Camp Century, Greenland (Dansgaard et al., 1969; Langway Jr, 2008). Subsequent cores from Antarctica extended this climatic record to 800,000 years (EPICA Community Members, 2004; Jouzel, 2013). Comparisons of air contained in these ice samples against measurements from the recent past enabled WGI AR5 to assess that atmospheric concentrations of CO_2, methane (CH_4), and nitrous oxide (N_2O) had all increased to levels unprecedented in at least the last 800,000 years (IPCC, 2013b) (see Section 1.2.1.2, Figure 1.5).

Global reconstructions of sea surface temperature were developed from material contained in deep-sea sediment cores (CLIMAP Project Members et al., 1976), providing the first quantitative constraints for model simulations of ice age climates (e.g., Rind and Peteet, 1985). Paleoclimate data and modelling showed that the Atlantic Ocean circulation has not been stable over glacial-interglacial time periods, and that many changes in ocean circulation are associated with abrupt transitions in climate in the North Atlantic region (Ruddiman and McIntyre, 1981; Broecker et al., 1985; Boyle and Keigwin, 1987; Manabe and Stouffer, 1988).

By the early 20th century, cyclical changes in insolation due to the interacting periodicities of orbital eccentricity, axial tilt, and axial precession had been hypothesised as a chief pacemaker of ice age-interglacial cycles on multi-millennial timescales (Milankovich, 1920). Paleoclimate information derived from marine sediment provides quantitative estimates of past temperature, ice volume, and sea level over millions of years (Section 1.2.1.2, Figure 1.5) (Emiliani, 1955; Shackleton and Opdyke, 1973; Siddall et al., 2003; Lisiecki and Raymo, 2005; Past Interglacials Working Group of PAGES, 2016). These estimates have bolstered the orbital cycles hypothesis (Hays et al., 1976; Berger, 1977, 1978). However, paleoclimatology of multi-million to billion-year periods reveals that methane, carbon dioxide, continental drift, silicate rock weathering, and other factors played a greater role than orbital cycles in climate changes during ice-free 'hothouse' periods of Earth's distant past (Frakes et al., 1992; Bowen et al., 2015; Zeebe et al., 2016).

The WGI AR5 (IPCC, 2013b) used paleoclimatic evidence to put recent warming and sea level rise in a multi-century perspective and assessed that 1983–2012 was *likely* the warmest 30-year period of the last 1400 years in the Northern Hemisphere (*medium confidence*). AR5 also assessed that the rate of sea level rise since the mid-19th century has been larger than the mean rate during the previous two millennia (*high confidence)*.

1.3.3 Lines of evidence: identifying natural and human drivers

The climate is a globally interconnected system driven by solar energy. Scientists in the 19th-century established the main physical principles governing Earth's temperature. By 1822, the principle of radiative

ACCEPTED VERSION SUBJECT TO FINAL EDITS

equilibrium (the balance between absorbed solar radiation and the energy Earth re-radiates into space) had been articulated, and the atmosphere's role in retaining heat had been likened to a greenhouse (Fourier, 1822). The primary explanations for natural climate change — greenhouse gases, orbital factors, solar irradiance, continental position, volcanic outgassing, silicate rock weathering, and the formation of coal and carbonate rock — were all identified by the late 1800s (Fleming, 1998; Weart, 2008).

The natural and anthropogenic factors responsible for climate change are known today as radiative 'drivers' or 'forcers'. The net change in the energy budget at the top of the atmosphere, resulting from a change in one or more such drivers, is termed radiative forcing (RF; see Annex VII: Glossary) and measured in Watts per square metre (W m^{-2}). The total radiative forcing over a given time interval (often since 1750) represents the sum of positive drivers (inducing warming) and negative ones (inducing cooling). Past IPCC reports have assessed scientific knowledge of these drivers, quantified their range for the period since 1750, and presented the current understanding of how they interact in the climate system. Like all previous IPCC reports, AR5 assessed that total radiative forcing has been positive at least since 1850–1900, leading to an uptake of energy by the climate system, and that the largest single contribution to total radiative forcing is the rising atmospheric concentration of CO_2 since 1750 (IPCC, 2013a; see Cross-Chapter Box 1.2 and Chapter 7).

Natural drivers include changes in solar irradiance, ocean currents, naturally occurring aerosols, and natural sources and sinks of radiatively active gases such as water vapour, carbon dioxide, methane, and sulphur dioxide. Detailed global measurements of surface-level solar irradiance were first conducted during the 1957–1958 International Geophysical Year (Landsberg, 1961), while top-of-atmosphere irradiance has been measured by satellites since 1959 (House et al., 1986). Measured changes in solar irradiance have been small and slightly negative since about 1980 (Matthes et al., 2017). Water vapour is the most abundant radiatively active gas, accounting for about 75% of the terrestrial greenhouse effect, but because its residence time in the atmosphere averages just 8–10 days, its atmospheric concentration is largely governed by temperature (van der Ent and Tuinenburg, 2017; Nieto and Gimeno, 2019). As a result, non-condensing greenhouse gases with much longer residence times serve as 'control knobs', regulating planetary temperature, with water vapour concentrations as a feedback effect (Lacis et al., 2010, 2013). The most important of these non-condensing gases is carbon dioxide (a positive driver), released naturally by volcanism at about 637 $MtCO_2$ yr^{-1} in recent decades, or roughly 1.6% of the 37 $GtCO_2$ emitted by human activities in 2018 (Burton et al., 2013; Le Quéré et al., 2018). Absorption by the ocean and uptake by plants and soils are the primary natural CO_2 sinks on decadal to centennial time scales (see Chapter 5, Section 5.1.2 and Figure 5.3).

Aerosols (tiny airborne particles) interact with climate in numerous ways, some direct (e.g. reflecting solar radiation back into space) and others indirect (e.g., cloud droplet nucleation); specific effects may cause either positive or negative radiative forcing. Major volcanic eruptions inject sulphur dioxide (SO_2, a negative driver) into the stratosphere, creating aerosols that can cool the planet for years at a time by reflecting some incoming solar radiation. The history and climatic effects of volcanic activity have been traced through historical records, geological traces, and observations of major eruptions by aircraft, satellites, and other instruments (Dörries, 2006). The negative RF of major volcanic eruptions was considered in the First Assessment Report (FAR; IPCC, 1990a). In subsequent assessments, the negative RF of smaller eruptions has also been considered (e.g., Chapter 2, section 2.4.3 in IPCC, 1995; Cross-Chapter Box 4.1 in Chapter 4 of this report). Dust and other natural aerosols have been studied since the 1880s (e.g., Aitken, 1889; Ångström, 1929, 1964; Twomey, 1959), particularly in relation to their role in cloud nucleation, an aerosol indirect effect whose RF may be either positive or negative depending on such factors as cloud altitude, depth, and albedo (Stevens and Feingold, 2009; Boucher et al., 2013).

Anthropogenic (human) drivers of climatic change were hypothesised as early as the 17th century, with a primary focus on forest clearing and agriculture (Grove, 1995; Fleming, 1998). In the 1890s, Arrhenius was first to calculate the effects of increased or decreased CO_2 concentrations on planetary temperature, and Högbom estimated that worldwide coal combustion of about 500 Mt yr^{-1} had already completely offset the natural absorption of CO_2 by silicate rock weathering (Högbom, 1894; Arrhenius, 1896; Berner, 1995; Crawford, 1997). As coal consumption reached 900 Mt yr^{-1} only a decade later, Arrhenius wrote that anthropogenic carbon dioxide from fossil fuel combustion might eventually warm the planet (Arrhenius, 1908). In 1938, analysing records from 147 stations around the globe, Callendar calculated atmospheric

ACCEPTED VERSION SUBJECT TO FINAL EDITS

warming over land at 0.3-0.4°C from 1880-1935 and attributed about half of this warming to anthropogenic CO_2 (Callendar, 1938; Fleming, 2007; Hawkins and Jones, 2013; Figure 1.8).

[START FIGURE 1.8 HERE]

Figure 1.8: G.S. Callendar's estimates of global land temperature variations and their possible causes. (a) The original figure from Callendar (1938), using measurements from 147 surface stations for 1880–1935, showing: (top) ten-year moving departures from the mean of 1901-1930 (°C), with the dashed line representing his estimate of the 'CO_2 effect' on temperature rise, and (bottom) annual departures from the 1901–1930 mean (°C). (b) Comparing the estimates of global land (60°S–60°N) temperatures tabulated in Callendar (1938, 1961) with a modern reconstruction (Osborn et al., 2021) for the same period, after (Hawkins and Jones (2013). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.8 HERE]

Studies of radiocarbon (^{14}C) in the 1950s established that increasing atmospheric CO_2 concentrations were due to fossil fuel combustion. Since all the ^{14}C once contained in fossil fuels long ago decayed into non-radioactive ^{12}C, the CO_2 produced by their combustion reduces the overall concentration of atmospheric ^{14}C (Suess, 1955). Related work demonstrated that while the ocean was absorbing around 30% of anthropogenic CO_2, these emissions were also accumulating in the atmosphere and biosphere (see Section 1.3.1 and Chapter 5, Section 5.2.1.5). Further work later established that atmospheric oxygen levels were decreasing in inverse relation to the anthropogenic CO_2 increase, because combustion of carbon consumes oxygen to produce CO_2 (Keeling and Shertz, 1992; IPCC, 2013a, Chapters 2 and 6). Revelle and Suess (1957) famously described fossil fuel emissions as a 'large scale geophysical experiment', in which 'within a few centuries we are returning to the atmosphere and ocean the concentrated organic carbon stored in sedimentary rocks over hundreds of millions of years'. The 1960s saw increasing attention to other radiatively active gases, especially ozone (Manabe and Möller, 1961; Plass, 1961). Methane and nitrous oxide were not considered systematically until the 1970s, when anthropogenic increases in those gases were first noted (Wang et al., 1976). In the 1970s and 1980s, scientists established that synthetic halocarbons (see Annex VII: Glossary), including widely used refrigerants and propellants, were extremely potent greenhouse gases (Ramanathan, 1975; Chapter 2, Section 2.2.4.3; Chapter 6, section 6.2.2.9). When these chemicals were also found to be depleting the stratospheric ozone layer, they were stringently and successfully regulated on a global basis by the 1987 Montreal Protocol on the Ozone Layer and successor agreements (Parson, 2003).

Radioactive fallout from atmospheric nuclear weapons testing (1940s–1950s) and urban smog (1950s–1960s) first provoked widespread attention to anthropogenic aerosols and ozone in the troposphere (Edwards, 2012). Theory, measurement, and modelling of these substances developed steadily from the 1950s (Hidy, 2019). However, the radiative effects of anthropogenic aerosols did not receive sustained study until around 1970 (Bryson and Wendland, 1970; Rasool and Schneider, 1971), when their potential as cooling agents was recognised (Peterson et al., 2008). The US Climatic Impact Assessment Program (CIAP) found that proposed fleets of supersonic aircraft, flying in the stratosphere, might cause substantial aerosol cooling and depletion of the ozone layer, stimulating efforts to understand and model stratospheric circulation, atmospheric chemistry, and aerosol radiative effects (Mormino et al., 1975; Toon and Pollack, 1976). Since the 1980s, aerosols have increasingly been integrated into comprehensive modelling studies of transient climate evolution and anthropogenic influences, through treatment of volcanic forcing, links to global dimming and cloud brightening, and their influence on cloud nucleation and other properties (e.g., thickness, lifetime, and extent) and precipitation (e.g., Hansen et al., 1981; Charlson et al., 1987, 1992; Albrecht, 1989; Twomey, 1991).

The FAR (1990) focused attention on human emissions of carbon dioxide, methane, tropospheric ozone, chlorofluorocarbons (CFCs), and nitrous oxide. Of these, at that time only the emissions of CO_2 and CFCs were well measured, with methane sources known only 'semi-quantitatively' (IPCC, 1990a). The FAR

ACCEPTED VERSION SUBJECT TO FINAL EDITS

assessed that some other trace gases, especially CFCs, have global warming potentials hundreds to thousands of times greater than CO_2 and methane, but are emitted in much smaller amounts. As a result, CO_2 remains by far the most important positive anthropogenic driver, with methane next most significant (Section 1.6.3); anthropogenic methane stems from such sources as fossil fuel extraction, natural gas pipeline leakage, agriculture, and landfills. In 2001, increased greenhouse forcing attributable to CO_2, methane, ozone, CFC-11, and CFC-12 was detected by comparing satellite measurements of outgoing longwave radiation measurements taken in 1970 and in 1997 (Harries et al., 2001). AR5 assessed that the 40% increase in atmospheric CO_2 contributed most to positive RF since 1750. Together, changes in atmospheric concentrations of CO_2, methane, nitrous oxide, and halocarbons from 1750–2011 were assessed to contribute a positive RF of 2.83 [2.26 to 3.40] W m^{-2} (IPCC, 2013b).

All IPCC reports have assessed the total RF as positive when considering all sources. However, due to the considerable variability of both natural and anthropogenic aerosol loads, the FAR characterised total aerosol RF as 'highly uncertain' and was unable even to determine its sign (positive or negative). Major advances in quantification of aerosol loads and their effects have taken place since then, and IPCC reports since 1992 have consistently assessed total forcing by anthropogenic aerosols as negative (IPCC, 1992, 1995a, 1996). However, due to their complexity and the difficulty of obtaining precise measurements, aerosol effects have been consistently assessed as the largest single source of uncertainty in estimating total RF (Stevens and Feingold, 2009; IPCC, 2013a). Overall, AR5 assessed that total aerosol effects, including cloud adjustments, resulted in a negative RF of –0.9 [–1.9 to −0.1] W m^{-2} (*medium confidence*), offsetting a substantial portion of the positive RF resulting from the increase in greenhouse gases (*high confidence*) (IPCC, 2013b). Chapter 7 provides an updated assessment of the total and per-component RF for the WGI contribution to AR6.

1.3.4 Lines of evidence: understanding and attributing climate change

Understanding the global climate system requires both theoretical understanding and empirical measurement of the major forces and factors that govern the transport of energy and mass (air, water and water vapour) around the globe; the chemical and physical properties of the atmosphere, ocean, cryosphere, and land surfaces; and the biological and physical dynamics of natural ecosystems, as well as the numerous feedbacks (both positive and negative) among these processes. Attributing climatic changes or extreme weather events to human activity (see Cross Working Group Box: Attribution) requires, additionally, understanding of the many ways that human activities may affect the climate, along with statistical and other techniques for separating the 'signal' of anthropogenic climate change from the 'noise' of natural climate variability (see Section 1.4.2). This inter- and trans-disciplinary effort requires contributions from many sciences.

Due to the complexity of many interacting processes ranging in scale from the molecular to the global, and occurring on timescales from seconds to millennia, attribution makes extensive use of conceptual, mathematical, and computer simulation models. Modelling allows scientists to combine a vast range of theoretical and empirical understanding from physics, chemistry, and other natural sciences, producing estimates of their joint consequences as simulations of past, present, or future states and trends (Nebeker, 1995; Edwards, 2010, 2011).

In addition to radiative transfer (discussed above in Section 1.3.3), forces and factors such as thermodynamics (energy conversions), gravity, surface friction, and the Earth's rotation govern the planetary-scale movements or 'circulation' of air and water in the climate system. The scientific theory of climate began with Halley (1686), who hypothesized vertical atmospheric circulatory cells driven by solar heating, and Hadley (1735), who showed how the Earth's rotation affects that circulation. Ferrel (1856) added the Coriolis force to existing theory, explaining the major structures of the global atmospheric circulation. In aggregate, prevailing winds and ocean currents move energy poleward from the equatorial regions where the majority of incoming solar radiation is received.

Climate models provide the ability to simulate these complex circulatory processes, and to improve the physical theory of climate by testing different mathematical formulations of those processes. Since controlled experiments at planetary scale are impossible, climate simulations provide one important way to

ACCEPTED VERSION SUBJECT TO FINAL EDITS

explore the differential effects and interactions of variables such as solar irradiance, aerosols, and greenhouse gases. To assess their quality, models or compontents of models may be compared with observations. For this reason, they can be used to attribute observed climatic effects to different natural and human drivers (Hegerl et al., 2011). As early as Arrhenius (1896), simple mathematical models were used to calculate the effects of doubling atmospheric carbon dioxide over pre-industrial concentrations (~550 ppm vs ~275 ppm). In the early 1900s Bjerknes formulated the Navier-Stokes equations of fluid dynamics for motion of the atmosphere (Bjerknes, 1906; Bjerknes et al., 1910), and Richardson (1922) developed a system for numerical weather prediction based on these equations. When electronic computers became available in the late 1940s, the methods of Bjerknes and Richardson were successfully applied to weather forecasting (Charney et al., 1950; Nebeker, 1995; Harper, 2008).

In the 1960s similar approaches to modelling the weather were used to model the climate, but with much longer runs than daily forecasting (Smagorinsky et al., 1965; Manabe and Wetherald, 1967). Simpler statistical and one- and two-dimensional modelling approaches continued in tandem with the more complex General Circulation Models (GCMs) (Manabe and Wetherald, 1967; Budyko, 1969; Sellers, 1969). The first coupled atmosphere-ocean model (AOGCM) with realistic topography appeared in 1975 (Bryan et al., 1975; Manabe et al., 1975). Rapid increases in computer power enabled higher resolutions, longer model simulations, and the inclusion of additional physical processes in GCMs, such as aerosols, atmospheric chemistry, sea ice, and snow.

In the 1990s, AOGCMs were state of the art. By the 2010s, Earth system models (ESMs, also known as coupled carbon-cycle climate models) incorporated land surface, vegetation, the carbon cycle, and other elements of the climate system. Since the 1990s, some major modelling centres have deployed 'unified' models for both weather prediction and climate modelling, with the goal of a seamless modelling approach that uses the same dynamics, physics, and parameterisations at multiple scales of time and space (Cullen, 1993; Brown et al., 2012; NRC Committee on a National Strategy for Advancing Climate Modeling, 2012; Brunet et al., 2015; Chapter 10, Section 10.1.2). Because weather forecast models make short-term predictions that can be frequently verified, and improved models are introduced and tested iteratively on cycles as short as 18 months, this approach allows major portions of the climate model to be evaluated as a weather model and more frequently improved. However, all climate models exhibit biases of different degrees and types, and the practice of 'tuning' parameter values in models to make their outputs match variables such as historical warming trajectories has generated concern throughout their history (Randall and Wielicki, 1997; Edwards, 2010; Hourdin et al., 2017; see also 1.5.3.2). Overall, the WGI AR5 assessed that climate models had improved since previous reports (IPCC, 2013b) .

Since climate models vary along many dimensions, such as grid type, resolution, and parameterizations, comparing their results requires special techniques. To address this problem, the climate modelling community developed increasingly sophisticated Model Intercomparison Projects (MIPs) (Gates et al., 1999; Covey et al., 2003). MIPs prescribe standardised experiment designs, time periods, output variables, or observational reference data, to facilitate direct comparison of model results. This aids in diagnosing the reasons for biases and other differences among models, and furthers process understanding (Section 1.5). Both the CMIP3 and CMIP5 model intercomparison projects included experiments testing the ability of models to reproduce 20th century global surface temperature trends both with and without anthropogenic forcings. Although some individual model runs failed to achieve this (Hourdin et al., 2017), the mean trends of multi-model ensembles did so successfully (Meehl et al., 2007a; Taylor et al., 2012). When only natural forcings were included (creating the equivalent of a 'control Earth' without human influences), similar multi-model ensembles could not reproduce the observed post-1970 warming at either global or regional scales (Edwards, 2010; Jones et al., 2013). The GCMs and ESMs compared in CMIP6 (used in this report) offer more explicit documentation and evaluation of tuning procedures (Schmidt et al., 2017; Burrows et al., 2018; Mauritsen and Roeckner, 2020); see Section 1.5).

The FAR (IPCC, 1990a) concluded that while both theory and models suggested that anthropogenic warming was already well underway, its signal could not yet be detected in observational data against the 'noise' of natural variability (also see Barnett and Schlesinger (1987) and Section 1.4.2). Since then, increased warming and progressively more conclusive attribution studies have identified human activities as

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the 'dominant cause of the observed warming since the mid-20th century' (IPCC, 2013b). 'Fingerprint' studies seek to detect specific observed changes – expected from theoretical understanding and model results – that could not be explained by natural drivers alone, and to attribute statistically the proportion of such changes that is due to human influence. These include global-scale surface warming, nights warming faster than days, tropospheric warming and stratospheric cooling, a rising tropopause, increasing ocean heat content, changed global patterns of precipitation and sea-level air pressure, increasing downward longwave radiation, and decreasing upward longwave radiation (Hasselmann, 1979; Schneider, 1994; Karoly et al., 1994; Santer et al., 1995, 2013, Hegerl et al., 1996, 1997; Gillett et al., 2003; Santer, 2003; Zhang et al., 2007; Stott et al., 2010; Davy et al., 2017; Mann et al., 2017). Cross Working Group Box 1.1 outlines attribution methods and uses from across the AR6, now including event attribution (specifying the influence of climate change on individual extreme events such as floods, or on the frequency of classes of events such as tropical cyclones). Overall, the evidence for human influence has grown substantially over time and from each IPCC report to the subsequent one.

A key indicator of climate understanding is whether theoretical climate system budgets or 'inventories', such as the balance of incoming and outgoing energy at the surface and at the top of the atmosphere, can be quantified and closed observationally. The global energy budget, for example, includes energy retained in the atmosphere, upper ocean, deep ocean, ice, and land surface. Church et al. (2013) assessed in AR5 with *high confidence* that independent estimates of effective radiative forcing (ERF), observed heat storage, and surface warming combined to give an energy budget for the Earth that is consistent with the WGI AR5 assessed *likely* range of equilibrium climate sensitivity (ECS) [1.5°C to 4.5°C] to within estimated uncertainties (IPCC, 2013a; on ECS, see Section 1.3.5 below). Similarly, over the period 1993 to 2010, when observations of all sea level components were available, WGI AR5 assessed the observed global mean sea level rise to be consistent with the sum of the observed contributions from ocean thermal expansion (due to warming) combined with changes in glaciers, the Antarctic and Greenland Ice Sheets, and land water storage (*high confidence*). Verification that the terms of these budgets balance over recent decades provides strong evidence for our understanding of anthropogenic climate change (Cross-Chapter Box 9.1 in Chapter 9).

The Appendix to Chapter 1 (Appendix 1A) lists the key detection and attribution statements in the Summaries for Policymakers of WGI reports since 1990. The evolution of these statements over time reflects the improvement of scientific understanding and the corresponding decrease in uncertainties regarding human influences. The SAR stated that 'the balance of evidence suggests a discernible human influence on global climate' (IPCC, 1995b). Five years later, the TAR concluded that 'there is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities' (IPCC, 2001b). AR4 further strengthened previous statements, concluding that 'most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations' (IPCC, 2007b). AR5 assessed that a human contribution had been detected to changes in warming of the atmosphere and ocean; changes in the global water cycle; reductions in snow and ice; global mean sea level rise; and changes in some climate extremes. AR5 concluded that 'it is *extremely likely* that human influence has been the dominant cause of the observed warming since the mid-20th century' (IPCC, 2013b).

1.3.5 Projections of future climate change

It was recognised in IPCC AR5 that information about the near term was increasingly relevant for adaptation decisions. In response, WGI AR5 made a specific assessment for how global surface temperature was projected to evolve over the next two decades, concluding that the change for the period 2016–2035 relative to 1986–2005 will *likely* be in the range of 0.3°C to 0.7°C (*medium confidence*), assuming no major volcanic eruptions or secular changes in total solar irradiance (IPCC, 2013b). AR5 was also the first IPCC assessment report to assess 'decadal predictions' of the climate, where the observed state of the climate system was used to start forecasts for a few years ahead. AR6 examines updates to these decadal predictions (Chapter 4, Section 4.4.1).

The assessments and predictions for the near-term evolution of global climate features are largely

ACCEPTED VERSION SUBJECT TO FINAL EDITS

independent of future carbon emissions pathways. However, WGI AR5 assessed that limiting climate change in the long-term future will require substantial and sustained reductions of greenhouse gas emissions (IPCC, 2013b). This assessment results from decades of research on understanding the climate system and its perturbations, and projecting climate change into the future. Each IPCC report has considered a range of emission scenarios, typically including a scenario in which societies choose to continue on their present course as well as several others reflecting socioeconomic and policy responses that may limit emissions and/or increase the rate of carbon dioxide removal from the atmosphere. Climate models are used to project the outcomes of each scenario. However, future human climate influence cannot be precisely predicted because greenhouse gas and aerosol emissions, land use, energy use, and other human activities may change in numerous ways. Common emission scenarios used in the WGI contribution to AR6 are detailed in Section 1.6.

Based on model results and steadily increasing CO_2 concentrations (Bolin and Bischof, 1970; SMIC, 1971; Meadows et al., 1972), concerns about future 'risk of effects on climate' were addressed in Recommendation 70 of the Stockholm Action Plan, resulting from the 1972 United Nations Conference on the Human Environment. Numerous other scientific studies soon amplified these concerns (summarised in Schneider (1975), and Williams (1978); see also Nordhaus (1975, 1977). In 1979, a US National Research Council (NRC) group led by Jule Charney reported on the 'best present understanding of the carbon dioxide/climate issue for the benefit of policymakers', initiating an era of regular and repeated large-scale assessments of climate science findings.

The 1979 Charney NRC report estimated equilibrium climate sensitivity (ECS) at 3°C, stating the range as 2°C–4.5°C, based on 'consistent and mutually supporting' model results and expert judgment (NRC, 1979). ECS is defined in IPCC assessments as the global surface air temperature (GSAT) response to CO_2 doubling (from pre-industrial levels) after the climate has reached equilibrium (stable energy balance between the atmosphere and ocean). Another quantity, transient climate response (TCR), was later introduced as the global surface air temperature change, averaged over a 20-year period, at the time of CO_2 doubling in a scenario of concentration increasing at 1% per year). Calculating ECS from historical or paleoclimate temperature records in combination with energy budget models has produced estimates both lower and higher than those calculated using GCMs and ESMs; in AR6, these are assessed in Chapter 7, Section 7.5.2.

ECS is typically characterised as most relevant on centennial timescales, while TCR was long seen as a more appropriate measure of the 50-100 year response to gradually increasing CO_2; however, recent studies have raised new questions about how accurately both quantities are estimated by GCMs and ESMs (Grose et al., 2018; Meehl et al., 2020; Sherwood et al., 2020). Further, as climate models evolved to include a full-depth ocean, the time scale for reaching full equilibrium became longer and new methods to estimate ECS had to be developed (Gregory et al., 2004; Meehl et al., 2020; Meinshausen et al., 2020). Because of these considerations as well as new estimates from observation-based, paleoclimate, and emergent-constraints studies (Sherwood et al., 2020), the AR6 definition of ECS has changed from previous reports; it now includes all feedbacks except those associated with ice sheets. Accordingly, unlike previous reports, the AR6 assessments of ECS and TCR are not based primarily on GCM and ESM model results (see Chapter 7, Box. 7.1 and Section 7.5.5 for a full discussion).

Today, other sensitivity terms are sometimes used, such as transient climate response to emissions (TCRE, defined as the ratio of warming to cumulative CO_2 emissions in a CO_2-only simulation) and Earth system sensitivity (ESS), which includes multi-century Earth system feedbacks such as changes in ice sheets. Table 1.2 shows estimates of ECS and TCR for major climate science assessments since 1979. The table shows that despite some variation in the range of GCM and (for the later assessments) ESM results, expert assessment of ECS changed little between 1979 and the present report. Based on multiple lines of evidence, AR6 has narrowed the *likely* range of ECS to 2.5-4.0 °C (Chapter 7, Section 7.5.5).

[START TABLE 1.2 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Table 1.2: Estimates of equilibrium climate sensitivity (ECS) and transient climate response (TCR) from successive major scientific assessments since 1979. No likelihood statements are available for reports prior to 2001 because those reports did not use the IPCC calibrated uncertainty language. The assessed range of ECS differs from the range derived from General Circulation Model (GCM) and Earth System Model (ESM) results because assessments take into account other evidence, other types of models, and expert judgment. The AR6 definition of ECS differs from previous reports, now including all long-term feedbacks except those associated with ice sheets. AR6 estimates of ECS are derived primarily from process understanding, historical observations, and emergent constraints, informed by (but not based on) GCM and ESM model results. CMIP6 is the 6th phase of the Coupled Model Intercomparison Project. See Chapter 7, Box 7.1 and Section 7.5.5.

Assessment	ECS range derived from GCM and ESM results (°C)	Assessed range of ECS (°C)	Assessed central estimate of ECS (°C)	Assessed range of TCR (°C)

[END TABLE 1.2 HERE]

WGI AR5 assessed that there is a close relationship of cumulative total emissions of CO_2 and global mean

ACCEPTED VERSION SUBJECT TO FINAL EDITS

surface temperature response that is approximately linear (IPCC, 2013b). This finding implies that continued emissions of carbon dioxide will cause further warming and changes in all components of the climate system, independent of any specific scenario or pathway. Scenario-based climate projections using the Representative Concentration Pathways (RCPs) assessed in WGI AR5 result in continued warming over the 21st century in all scenarios except a strong climate change mitigation scenario (RCP2.6). Similarly, under all RCP scenarios, AR5 assessed that the rate of sea level rise over the 21st century will *very likely* exceed that observed during 1971–2010 due to increased ocean warming and increased loss of mass from glaciers and ice sheets. Further increases in atmospheric CO_2 will also lead to further uptake of carbon by the ocean, which will increase ocean acidification. By the mid-21st century the magnitudes of the projected changes are substantially affected by the choice of scenario. The set of scenarios used in climate change projections assessed as part of the AR6 are discussed in Section 1.6.

From the close link between cumulative emissions and warming it follows that any given level of global warming is associated with a total budget of GHG emissions, especially CO_2 as it is the largest long-lasting contributor to radiative forcing (Allen et al., 2009; Collins et al., 2013; Rogelj et al., 2019). Higher emissions in earlier decades imply lower emissions later on to stay within the Earth's carbon budget. Stabilising the anthropogenic influence on global surface temperature thus requires that CO_2 emissions and removals reach net zero once the remaining carbon budget is exhausted (see Cross-Chapter Box 1.4).

Past, present and future emissions of CO_2 therefore commit the world to substantial multi-century climate change, and many aspects of climate change would persist for centuries even if emissions of CO_2 were stopped immediately (IPCC, 2013b). According to AR5, a large fraction of this change is essentially irreversible on a multi-century to millennial time scale, barring large net removal ('negative emissions') of CO_2 from the atmosphere over a sustained period through as yet unavailable technological means (IPCC, 2013a, 2018; see Chapters 4 and 5). However, significant reductions of warming due to SLCFs could reduce the level at which temperature stabilises once CO_2 emissions reach net zero, and also reduce the long-term global warming commitment by reducing radiative forcing from SLCFs (Chapter 5).

In summary, major lines of evidence – observations, paleoclimate, theoretical understanding, and natural and human drivers — have been studied and developed for over 150 years. Methods for projecting climate futures have matured since the 1950s and attribution studies since the 1980s. We conclude that understanding of the principal features of the climate system is robust and well established.

1.3.6 How do previous climate projections compare with subsequent observations?

Many different sets of climate projections have been produced over the past several decades, so it is valuable to assess how well those projections have compared against subsequent observations. Consisent findings build confidence in the process of making projections for the future. For example, Stouffer and Manabe (2017) compared projections made in the early 1990s with subsequent observations. They found that the projected surface pattern of warming, and the vertical structure of temperature change in both the atmosphere and ocean, were realistic. Rahmstorf et al. (2007, 2012) examined projections of global surface temperatureand global mean sea level assessed by the TAR and AR4 and found that the global surface temperature projections were in good agreement with the subsequent observations, but that sea level projections were underestimates compared to subsequent observations. WGI AR5 also examined earlier IPCC Assessment Reports to evaluate their projections of how global surface temperature and global mean sea level would change (Cubasch et al., 2013) with similar conclusions.

Although these studies generally showed good agreement between the past projections and subsequent observations, this type of analysis is complicated because the scenarios of future radiative forcing used in earlier projections do not precisely match the actual radiative forcings that subsequently occurred. Mismatches between the projections and subsequent observations could be due to incorrectly projected radiative forcings (e.g., aerosol emissions, greenhouse gas concentrations or volcanic eruptions that were not included), an incorrect modelled response to those forcings, or both. Alternatively, agreement between projections and observations may be fortuitous due to a compensating balance of errors, for example, too low

ACCEPTED VERSION SUBJECT TO FINAL EDITS

climate sensitivity but too strong radiative forcings.

One approach to partially correct for mismatches between the forcings used in the projections and the forcings that actually occurred is described by Hausfather et al. (2020). Model projections of global surface temperatureand estimated radiative forcings were taken from several historical studies, along with the baseline no-policy scenarios from the first four IPCC assessment reports. These model projections of temperature and radiative forcing are then compared to (a) the observed change in temperature through time over the projection period, and (b) the observed change in temperature relative to the observationally-estimated radiative forcing over the projection period (Figure 1.9; data from Hausfather et al. (2020)).

Although this approach has limitations when the modelled forcings differ greatly from the forcings subsequently experienced, they were generally able to project actual future global warming when the mismatches between forecast and observed radiative forcings are accounted for. For example, the Scenario B presented in Hansen et al. (1988) projected around 50% more warming than has been observed during the 1988–2017 period, but this is largely because it overestimated subsequent radiative forcings. Similarly, while the FAR (IPCC, 1990a) projected a higher rate of global surface temperature warming than has been observed, this is largely because it overestimated future greenhouse gas concentrations: the FAR's projected increase in total anthropogenic forcing between 1990 and 2017 was 1.6 W m^{-2}, while the observational estimate of actual forcing during that period is 1.1 W m^{-2} (Dessler and Forster, 2018). Under these actual forcings, the change in temperature in the FAR aligns with observations (Hausfather et al., 2020).

[START FIGURE 1.9 HERE]

Figure 1.9: Assessing past projections of global temperature change. Projected temperature change post-publication on a temperature vs time (1970–2020, top panel) and temperature vs radiative forcing (1970–2017, bottom panel) basis for a selection of prominent climate model projections (taken from Hausfather et al., 2020). Model projections (using global surface air temperature, GSAT) are compared to temperature observations (using global mean surface temperature, GMST) from HadCRUT5 (black) and anthropogenic forcings (through 2017) from Dessler and Forster (2018), and have a baseline generated from the first five years of the projection period. Projections shown are: Manabe (1970), Rasool and Schneider (1971), Broecker (1975), Nordhaus (1977), Hansen et al. (1981, H81), Hansen et al. (1988, H88), Manabe and Stouffer (1993), along with the Energy Balance Model (EBM) projections from the FAR, SAR and TAR, and the multi-model mean projection using CMIP3 simulations of the Special Reports on Emission Scenarios (SRES) A1B scenario from AR4. H81 and H88 show most excpected scenarios 1 and B, respectively. See Hausfather et al. (2020) for more details of the projections. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.9 HERE]

In addition to global surface temperature, past regional projections can be evaluated. For example, the FAR presented a series of temperature projections for 1990 to 2030 for several regions around the world. Regional projections were given for a best global warming estimate of 1.8°C since 1850-1900 by 2030, and were assigned *low confidence*. The FAR also suggested that regional temperature changes should be scaled by -30% to +50% to account for the uncertainty in projected global warming.

The regional projections presented in the FAR are compared to the observed temperature change in the period since 1990 (Figure 1.10), following Grose et al. (2017). Subsequent observed temperature change has tracked within the FAR projected range for the best estimate of regional warming in the Sahel, South Asia and Southern Europe. Temperature change has tracked at or below this range for the Central North America and Australia, yet remains within the range reduced by 30% to generate the FAR's lower global warming estimate, consistent with the smaller observed estimate of radiative forcing compared to the FAR central estimate. Note that the projections assessed in Chapter 4 of AR6 WGI suggest that global temperatures will be around 1.2°C–1.8°C above 1850–1900 by 2030, also lower than the FAR central estimate.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Overall, there is *medium confidence* that past projections of global temperature are consistent with subsequent observations, especially when accounting for the difference in radiative forcings used and those which actually occurred (*limited evidence, high agreement*). FAR regional projections are broadly consistent with subsequent observations, allowing for regional-scale climate variability and differences in projected and actual forcings. There is *medium confidence* that the spatial warming pattern has been reliably projected in past IPCC reports (*limited evidence, high agreement*).

[START FIGURE 1.10 HERE]

Figure 1.10: Range of projected temperature change for 1990–2030 for various regions defined in IPCC First Assessment Report (FAR). The left panel shows the FAR projections (IPCC, 1990a) for Southern Europe, with darker red bands representing the range of projected change given for the best estimate of 1.8°C global warming since pre-industrial to 2030, and the fainter red bands show the range scaled by –30% to +50% for lower and higher estimates of global warming. Blue lines show the regionally averaged observations from several global temperature gridded datasets, and blue dashed lines show the linear trends in those datasets for 1990–2020 extrapolated to 2030. Observed datasets are: HadCRUT5, Cowtan and Way, GISTEMP, Berkeley Earth and NOAA GlobalTemp. The inset map shows the definition of the FAR regions used. The right panel shows projected temperature changes by 2030 for the various FAR regions, compared to the extrapolated observational trends, following Grose et al. (2017). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.10 HERE]

[START BOX 1.2 HERE]

Box 1.2: Special Reports in the sixth IPCC assessment cycle: key findings

The Sixth Assessment Cycle started with three Special Reports. The Special Report on Global Warming of 1.5°C (SR1.5, (IPCC, 2018), invited by the Parties to the UNFCCC in the context of the Paris Agreement, assessed current knowledge on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas (GHG) emission pathways. The Special Report on Climate Change and Land (SRCCL, IPCC, 2019a) addressed GHG fluxes in land-based ecosystems, land use and sustainable land management in relation to climate change adaptation and mitigation, desertification, land degradation and food security. The Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC, IPCC, 2019b) assessed new literature on observed and projected changes of the ocean and the cryosphere, and their associated impacts, risks, and responses.

The SR1.5 and SRCCL were produced through a collaboration between the three IPCC Working Groups, the SROCC by only WGs I and II. Here we focus on key findings relevant to the physical science basis covered by WGI.

1) Observations of climate change

The SR1.5 estimated with *high confidence* that human activities caused a global warming of approximately 1°C between the 1850-1900 and 2017. For the period 2006–2015, observed global mean surface temperature (GMST[7]) was 0.87±0.12°C higher than the average over the 1850–1900 period (*very high confidence*). Anthropogenic global warming was estimated to be increasing at 0.2±0.1°C per decade *(high confidence)* and *likely* matches the level of observed warming to within ±20%. The SRCCL found with *high confidence* that over land, mean surface air temperature increased by 1.53±0.15°C from 1850–1900 to 2006–2015, or nearly twice as much as the global average. This observed warming has already led to increases in the

[7] Box 1.2 reproduces the temperature metrics as they appeared in the respective SPMs of the SRs. In AR6 long-term changes of GMST (Global Mean Surface Temperature) and GSAT (Global Surface Air Temperature) are considered to be equivalent, differing in uncertainty estimates only (see Cross-Chapter Box 2.3 in Chapter 2).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

frequency and intensity of climate and weather extremes in many regions and seasons, including heat waves in most land regions (*high confidence*), increased droughts in some regions (*medium confidence*), and increases in the intensity of heavy precipitation events at the global scale (*medium confidence*). These climate changes have contributed to desertification and land degradation in many regions (*high confidence*). Increased urbanisation can enhance warming in cities and their surroundings (heat island effect), especially during heat waves (*high confidence),* and intensify extreme rainfall (*medium confidence*).

With respect to the ocean, the SROCC assessed that it is *virtually certain* that the ocean has warmed unabated since 1970 and has taken up more than 90% of the excess heat contributed by global warming. The rate of ocean warming has *likely* more than doubled since 1993. Over the period 1982–2016, marine heatwaves have *very likely* doubled in frequency and are increasing in intensity (*very high confidence*). In addition, the surface ocean acidified further (*virtually certain*) and loss of oxygen occurred from the surface to a depth of 1000 m (*medium confidence*). The report expressed *medium confidence* that the Atlantic Meridional Overturning Circulation (AMOC) weakened in 2004–2017 relative to 1850–1900.

Concerning the cryosphere, the SROCC reported widespread continued shrinking of nearly all components. Mass loss from the Antarctic Ice Sheet tripled over the period 2007–2016 relative to 1997–2006, while mass loss doubled for the Greenland Ice Sheet (*likely, medium confidence*). The report concludes with *very high confidence* that due to the combined increased loss from the ice sheets, global mean sea level (GMSL) rise has accelerated (*extremely likely*). The rate of recent GMSL rise (3.6±0.5 mm yr^{-1} for 2006–2015) is about 2.5 times larger than for 1901–1990. The report also found that Arctic sea ice extent has *very likely* decreased for all months of the year since 1979 and that September sea ice reductions of 12.8±2.3% per decade are *likely* unprecedented for at least 1000 years. Feedbacks from the loss of summer sea ice and spring snow cover on land have contributed to amplified warming in the Arctic (*high confidence*), where surface air temperature *likely* increased by more than double the global average over the last two decades. By contrast, Antarctic sea ice extent overall saw no statistically significant trend for the period 1979 to 2018 (*high confidence*).

The SROCC assessed that anthropogenic climate change has increased observed precipitation (*medium confidence*), winds (*low confidence*), and extreme sea level events (*high confidence*) associated with some tropical cyclones. It also found evidence for an increase in annual global proportion of Category 4 or 5 tropical cyclones in recent decades (*low confidence*).

2) Drivers of climate change

The SRCCL stated that the land is simultaneously a source and sink of CO_2 due to both anthropogenic and natural drivers. It estimates with *medium confidence* that Agriculture, Forestry and Other Land Use (AFOLU) activities accounted for around 13% of CO_2, 44% of methane, and 82% of nitrous oxide emissions from human activities during 2007–2016, representing 23% (12.0±3.0 $GtCO_2$ equivalent yr^{-1}) of the total net anthropogenic emissions of GHGs. The natural response of land to human-induced environmental change such as increasing atmospheric CO_2 concentration, nitrogen deposition, and climate change, caused a net CO_2 sink equivalent of around 29% of total CO_2 emissions (*medium confidence*); however, the persistence of the sink is uncertain due to climate change (*high confidence*).

The SRCCL also assessed how changes in land conditions affect global and regional climate. It found that changes in land cover have led to both a net release of CO_2, contributing to global warming, and an increase in global land albedo, causing surface cooling. However, the report estimated that the resulting net effect on globally averaged surface temperature was small over the historical period (*medium confidence*).

The SROCC found that the carbon content of Arctic and boreal permafrost is almost twice that of the atmosphere (*medium confidence)*, and assessed *medium evidence* with *low agreement* that thawing northern permafrost regions are currently releasing additional net methane and CO_2.

3) Projections of climate change

ACCEPTED VERSION SUBJECT TO FINAL EDITS

The SR1.5 concluded that global warming is *likely* to reach 1.5°C between 2030 and 2052 if it continues to increase at the current rate (*high confidence*). However, even though warming from anthropogenic emissions will persist for centuries to millennia and will cause ongoing long-term changes, past emissions alone are *unlikely* to raise global surface temperatur to 1.5°C above 1850-1900 levels.

The SR1.5 also found that reaching and sustaining net zero anthropogenic CO_2 emissions and reducing net non-CO_2 radiative forcing would halt anthropogenic global warming on multi-decadal time scales (*high confidence*). The maximum temperature reached is then determined by cumulative net global anthropogenic CO_2 emissions up to the time of net zero CO_2 emissions (*high confidence*) and the level of non-CO_2 radiative forcing in the decades prior to the time that maximum temperatures are reached (*medium confidence*).

Furthermore, climate models project robust differences in regional climate characteristics between the present day and a global warming of 1.5°C, and between 1.5°C and 2°C, including mean temperature in most land and ocean regions and hot extremes in most inhabited regions (*high confidence*). There is *medium confidence* in robust differences in heavy precipitation events in several regions and the probability of droughts in some regions.

The SROCC projected that global-scale glacier mass loss, permafrost thaw, and decline in snow cover and Arctic sea ice extent will continue in the near term (2031–2050) due to surface air temperature increases (*high confidence*). The Greenland and Antarctic Ice Sheets are projected to lose mass at an increasing rate throughout the 21st century and beyond (*high confidence*). Sea level rise will also continue at an increasing rate. For the period 2081–2100 with respect to 1986–2005, the *likely* ranges of global mean sea level (GMSL) rise are projected at 0.26–0.53 m for RCP2.6 and 0.51–0.92 m for RCP8.5. For the RCP8.5 scenario, projections of GMSL rise by 2100 are higher by 0.1 m than in AR5 due to a larger contribution from the Antarctic Ice Sheet (*medium confidence*). Extreme sea level events that occurred once per hundred years in the recent past are projected to occur at least once per year at many locations by 2050, especially in tropical regions, under all RCP scenarios *(high confidence*). According to SR1.5, by 2100, GMSL rise would be around 0.1 m lower with 1.5°C global warming compared to 2°C (*medium confidence*). If warming is held to 1.5°, GMSLwill still continue to rise well beyond 2100, but at a slower rate and a lower magnitude. However, instability and/or irreversible loss of the Greenland and Antarctic Ice Sheets, resulting in multi-metre rise in sea level over hundreds to thousands of years, could be triggered at 1.5°C to 2°C of global warming (*medium confidence*). According to the SROCC, sea level rise in an extended RCP2.6 scenario would be limited to around 1 m in 2300 (*low confidence*) while multi-metre sea-level rise is projected under RCP8.5 by then (*medium confidence*).

The SROCC projected that over the 21st century, the ocean will transition to unprecedented conditions with increased temperatures (*virtually certain*), further acidification (*virtually certain*), and oxygen decline (*medium confidence*). Marine heatwaves are projected to become more frequent (*very high confidence*) as are extreme El Niño and La Niña events (*medium confidence*). The AMOC is projected to weaken during the 21st century (*very likely*), but a collapse is deemed *very unlikely* (albeit with *medium confidence* due to known biases in the climate models used for the assessment).

4) Emission pathways to limit global warming

The SR1.5 focused on emission pathways and system transitions consistent with 1.5°C global warming over the 21st century. Building upon the understanding from WGI AR5 of the quasi-linear relationship between cumulative net anthropogenic CO_2 emissions since 1850–1900 and maximum global mean temperature, the report assessed the remaining carbon budgets compatible with the 1.5°C or 2°C warming goals of the Paris Agreement. Starting from year 2018, the remaining carbon budget for a one-in-two chance of limiting global warming to 1.5°C is about 580 $GtCO_2$, and about 420 $GtCO_2$ for a two-in-three chance (*medium confidence*). At constant 2017 emissions, these budgets would be depleted by about the years 2032 and 2028, respectively. Using GMST instead of GSAT gives estimates of 770 and 570 $GtCO_2$, respectively (*medium confidence*). Each budget is further reduced by approximately 100 $GtCO_2$ over the course of this century when permafrost and other less well represented Earth-system feedbacks are taken into account.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

It is concluded that all emission pathways with no or limited overshoot of 1.5°C imply that global net anthropogenic CO_2 emissions would need to decline by about 45% from 2010 levels by 2030, reaching net zero around 2050, together with deep reductions in other anthropogenic emissions, such as methane and black carbon. To limit global warming to below 2°C, CO_2 emissions would have to decline by about 25% by 2030 and reach net zero around 2070.

[END BOX 1.2 HERE]

1.4 AR6 foundations and concepts

AR6 WGI builds on previous assessments using well established foundations and concepts. This section highlights some of the cross-cutting methods applied in the climate change literature and topics discussed repeatedly throughout this report. The choices related to baseline, or reference periods, are first highlighted (Section 1.4.1), including a specific discussion on the pre-industrial baseline used in AR6 WGI (Cross-Chapter Box 1.2). The relationships between long-term trends, climate variability and the concept of emergence of changes (Section 1.4.2) and the sources of uncertainty in climate simulations (Section 1.4.3) are discussed next. The topic of low-likelihood outcomes, storylines, abrupt changes and surprises follows (Section 1.4.4), including a description of the AR6 WGI risk framing (Cross-Chapter Box 1.3). The Cross-Working Group Box: Attribution describes attribution methods, including those for extreme events. Various sets of geographical regions used in later Chapters are also defined and introduced (Section 1.4.5).

1.4.1 Baselines, reference periods and anomalies

Several 'baselines' or 'reference periods' are used consistently throughout AR6 WGI. Baseline refers to a period against which differences are calculated whereas reference period is used more generally to indicate a time period of interest, or a period over which some relevant statistics are calculated (see Annex VII: Glossary). Variations in observed and simulated climate variables over time are often presented as 'anomalies', i.e., the differences relative to a baseline, rather than using the absolute values. This is done for several reasons.

First, anomalies are often used when combining data from multiple locations, because the absolute values can vary over small spatial scales which are not densely observed or simulated, whereas anomalies are representative for much larger scales (e.g., for temperature, Hansen and Lebedeff 1987). Since their baseline value is zero by definition, anomalies are also less susceptible to biases arising from changes in the observational network. Second, the seasonality in different climate indicators can be removed using anomalies to more clearly distinguish variability from long-term trends.

Third, different datasets can have different absolute values for the same climate variable that should be removed for effective comparisons of variations with time. This is often required when comparing climate simulations with each other, or when comparing simulations with observations, as simulated climate variables are also affected by model bias that can be removed when they are presented as anomalies. It can also be required when comparing observational datasets or reanalyses (see Section 1.5.2) with each other, due to systematic differences in the underlying measurement system (see Figure 1.11). Understanding the reasons for any absolute difference is important, but whether the simulated absolute value matters when projecting future change will depend on the variable of interest. For example, there is not a strong relationship between climate sensitivity of a model (which is an indicator of the degree of future warming) and the simulated absolute global surface temperature (Mauritsen et al. 2012; Hawkins and Sutton 2016).

For some variables, such as precipitation, anomalies are often expressed as percentages in order to more easily compare changes in regions with very different climatological means. However, for situations where there are important thresholds (e.g., phase transitions around 0°C) or for variables which can only take a particular sign or be in a fixed range (e.g., sea ice extent or relative humidity), absolute values are normally used.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

The choice of a baseline period has important consequences for evaluating both observations and simulations of the climate, for comparing observations with simulations, and for presenting climate projections. There is usually no perfect choice of baseline as many factors have to be considered and compromises may be required (Hawkins and Sutton 2016). It is important to evaluate the sensitivity of an analysis or assessment to the choice of the baseline.

For example, the collocation of observations and reanalyses within the model ensemble spread depends on the choice of the baseline, and uncertainty in future projections of climate is reduced if using a more recent baseline, especially for the near-term (Figure 1.11). The length of an appropriate baseline or reference period depends on the variable being considered, the rates of change of the variable and the purpose of the period, but is usually 20 to 50 years long. The World Meteorological Organization (WMO) uses 30-year periods to define 'climate normals', which indicate conditions expected to be experienced in a given location.

[START FIGURE 1.11 HERE]

Figure 1.11: Choice of baseline matters when comparing observations and model simulations. Global surface air temperature (GSAT, grey) from a range of CMIP6 historical simulations (1850–2014, 25 models) and SSP1-2.6 (2015–2100) using absolute values (top) and anomalies relative to two different baselines: 1850–1900 (middle) and 1995–2014 (bottom). An estimate of GSAT from a reanalysis (ERA-5, orange, 1979–2020) and an observation-based estimate of global mean surface air temperature (GMST) (Berkeley Earth, black, 1850–2020) are shown, along with the mean GSAT for 1961–1990 estimated by Jones et al. (1999), light blue shading, 14.0±0.5°C). Using the more recent baseline (bottom) allows the inclusion of datasets which do not include the periods of older baselines. The middle and bottom panels have scales which are the same size but offset. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.11 HERE]

For AR6 WGI, the period 1995–2014 is used as a baseline to calculate the changes in future climate using model projections and also as a 'modern' or 'recent past' reference period when estimating past observed warming. The equivalent period in AR5 was 1986–2005, and in SR1.5, SROCC and SRCCL it was 2006–2015. The primary reason for the different choice in AR6 is that 2014 is the final year of the historical CMIP6 simulations. These simulations subsequently assume different emission scenarios and so choosing any later baseline end date would require selecting a particular emissions scenario. For certain assessments, the most recent decade possible (e.g. 2010–2019 or 2011–2020, depending on the availability of observations) is also used as a reference period (see Cross Chapter Box 2.3 in Chapter 2).

Figure 1.12 shows changes in observed global mean surface temperature (GMST) relative to 1850–1900 and illustrates observed global warming levels for a range of reference periods that are either used in AR6 or were used in previous IPCC Reports. This allows changes to be calculated between different periods and compared to previous assessments. For example, AR5 assessed the change in GMST from the 1850–1900 baseline to 1986–2005 reference period as 0.61 (0.55–0.67) °C, whereas it is now assessed to be 0.69 (0.52–0.82) °C using improved GMST datasets (also see Cross-Chapter Box 2.3 in Chapter 2).

The commonly used metric for global surface warming tends to be global mean surface temperature (GMST) but, as shown in Figure 1.11, climate model simulations tend to use global surface air temperature (GSAT). Although GMST and GSAT are closely related, the two measures are physically distinct. GMST is a combination of land surface air temperatures (LSAT) and sea surface temperatures (SSTs), whereas GSAT is surface air temperatures over land, ocean and ice. A key development in AR6 is the assessment that long-term changes in GMST and GSAT differ by at most 10% in either direction, with *low confidence* in the sign of any differences (see Cross Chapter Box 2.3 for details).

Three future reference periods are used in AR6 WGI for presenting projections: *near-term* (2021–2040),

ACCEPTED VERSION SUBJECT TO FINAL EDITS

mid-term (2041–2060) and *long-term* (2081–2100) (see Figure 1.11). In AR6, 20-year reference periods are considered long enough to show future changes in many variables when averaging over ensemble members of multiple models, and short enough to enable the time dependence of changes to be shown throughout the 21st century. Projections with alternative recent baselines (such as 1986–2005 or the current WMO climate normal period of 1981–2010) and a wider range of future reference periods are presented in the Interactive Atlas. Note that 'long-term' is also sometimes used to refer to durations of centuries to millennia when examining past climate, as well as future climate change beyond the year 2100. Cross-Chapter Box 2.1 in Chapter 2 discusses the paleo reference periods used in AR6.

[START FIGURE 1.12 HERE]

Figure 1.12: Global warming over the instrumental period. Observed global mean surface temperature (GMST) from four datasets, relative to the average temperature of 1850–1900 in each dataset (see Cross-Chapter Box 2.3 and Section 2.3.1.1 for more details). The shaded grey band indicates the assessed *likely* range for the period around 1750 (see Cross-Chapter Box 1.2). Different reference periods are indicated by the coloured horizontal lines, and an estimate of total GMST change up to that period is given, enabling a translation of the level of warming between different reference periods. The reference periods are all chosen because they have been used in the AR6 or previous IPCC assessment reports. The value for the 1981–2010 reference period, used as a 'climate normal' period by the World Meteorological Organization, is the same as the 1986–2005 reference period shown. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.12 HERE]

[START CROSS-CHAPTER BOX 1.2 HERE]

Cross-Chapter Box 1.2: Changes in global temperature between 1750 and 1850

Contributing Authors: Ed Hawkins (UK), Paul Edwards (USA), Piers Forster (UK), Darrell Kaufman (USA), Jochem Marotzke (Germany), Malte Meinshausen (Australia/Germany), Maisa Rojas (Chile), Bjørn H. Samset (Norway), Peter Thorne (Ireland/UK).

The Paris Agreement aims to limit global temperatures to specific thresholds '*above pre-industrial levels*'. In AR6 WGI, as in previous IPCC reports, observations and projections of changes in global temperature are generally expressed relative to 1850–1900 as an approximate pre-industrial state (SR1.5, IPCC, 2018). This is a pragmatic choice based upon data availability considerations, though both anthropogenic and natural changes to the climate occurred before 1850. The remaining carbon budgets, the chance of crossing global temperature thresholds, and projections of extremes and sea level rise at a particular level of global warming can all be sensitive to the chosen definition of the approximate pre-industrial baseline (Millar et al., 2017a; Schurer et al., 2017; Pfleiderer et al., 2018; Rogelj et al., 2019; Tokarska et al., 2019). This Cross-Chapter Box assesses the evidence on change in radiative forcing and global temperature from the period around 1750 to 1850–1900; variations in the climate before 1750 are discussed in Chapter 2.

Although there is some evidence for human influence on climate before 1750 (e.g., Ruddiman and Thomson, 2001; Koch et al., 2019), the magnitude of the effect is still disputed (e.g., Joos et al., 2004; Beck et al., 2018b; see Chapter 5, Section 5.1.2.3), and most studies analyse the human influence on climate over the industrial period. Historically, the widespread use of coal-powered machinery started the Industrial Revolution in Britain in the late 18th century (Ashton, 1997), but the global effects were small for several decades. In line with this, previous IPCC assessment reports considered changes in radiative forcing relative to 1750, and temperature changes were often reported relative to the 'late 19th century'. AR5 and SR1.5 made the specific pragmatic choice to approximate pre-industrial global temperatures by the average of the 1850–1900 period, when permanent surface observing networks emerged that provide sufficiently accurate

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and continuous measurements on a near-global scale (see Sections 1.3.1 and Chapter 2, Section 2.3.1.1), and because the model simulations of the historical period used 1850 as their start date. For the same reasons, to ensure continuity with previous assessments, and because of larger uncertainties and lower confidence in climatic changes before 1850 than after, AR6 makes the same choice to approximate pre-industrial global temperatures by the average of the 1850-1900 period.

Here we assess improvements in our understanding of climatic changes in the period 1750-1850. Anthropogenic influences on climate between 1750 and 1900 were primarily increased anthropogenic GHG and aerosol emissions, and changes in land use. Between 1750 and 1850 atmospheric CO_2 levels increased by from about 278 ppm to about 285 ppm (Chapter 2, Section 2.2.3, equivalent to around 3 years of current rates of increase), corresponding to about 55 $GtCO_2$ in the atmosphere. Estimates of emissions from fossil fuel burning (about 4 $GtCO_2$, Boden et al., 2017) cannot explain the pre-1850 increase, so CO_2 emissions from land use changes are implicated as the dominant source. The atmospheric concentration of other GHGs also increased over the same period, and there was a cooling influence from other anthropogenic radiative forcings (such as aerosols and land use changes), but with a larger uncertainty than for GHGs (e.g., Carslaw et al., 2017; Owens et al., 2017; Hamilton et al., 2018; Chapter 2, Section 2.2.6; Chapter 7, Section 7.3.5.2; Cross-Chapter Box 1.2, Figure 1). It is *likely* that there was a net anthropogenic forcing of 0.0–0.3 Wm^{-2} in 1850–1900 relative to 1750 (*medium confidence*). The net radiative forcing from changes in solar activity and volcanic activity in 1850–1900, compared to the period around 1750, is estimated to be smaller than ± 0.1 W m^{-2}, but note there were several large volcanic eruptions between 1750 and 1850 (Cross-Chapter Box 1.2, Figure 1).

Several studies since AR5 have estimated changes in global temperatures following industrialisation and before 1850. Hawkins et al. (2017) used observations, radiative forcing estimates and model simulations to estimate the warming from 1720–1800 until 1986–2005 and assessed a *likely* range of 0.55°C–0.80°C, slightly broader than the equivalent range starting from 1850–1900 (0.6°C–0.7°C). From proxy evidence, PAGES 2k Consortium (2019) found that GMST for 1850–1900 was 0.02°C [-0.22 to 0.16°C] warmer than the 30-year period centred on 1750. Schurer et al. (2017) used climate model simulations of the last millennium to estimate that the increase in GHG concentrations before 1850 caused an additional *likely* range of 0.0–0.2°C global warming when considering multiple reference periods. Haustein et al. (2017) implies an additional warming of around 0.05°C attributable to human activity from 1750 to 1850–1900, and the AR6 emulator (Chapter 7, Section 7.3.5.3) estimates the *likely* range of this warming to be 0.04°C–0.14°C.

Combining these different sources of evidence, we assess that from the period around 1750 to 1850–1900 there was a change in global temperature of around 0.1°C [-0.1 to +0.3°C](*medium confidence*), with an anthropogenic component of a *likely* range of 0.0°C–0.2°C (*medium confidence*).

[START CROSS-CHAPTER BOX1.2, FIGURE 1 HERE]

Cross-Chapter Box 1.2, Figure 1: **Changes in radiative forcing from 1750 to 2019**. The radiative forcing estimates from the AR6 emulator (see Cross-Chapter Box 7.1 in Chapter 7) are split into GHG, other anthropogenic (mainly aerosols and land use) and natural forcings, with the average over the 1850–1900 baseline shown for each. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE CROSS-CHAPTER 1.2, FIGURE 1 HERE]

[END CROSS-CHAPTER BOX 1.2 HERE]

1.4.2 Variability and emergence of the climate change signal

Climatic changes since the pre-industrial era are a combination of long-term anthropogenic changes and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

natural variations on time scales from days to decades. The relative importance of these two factors depends on the climate variable or region of interest. Natural variations consist of both natural radiatively forced trends (e.g. due to volcanic eruptions or solar variations) and 'internal' fluctuations of the climate system which occur even in the absence of any radiative forcings. The internal 'modes of variability', such as ENSO and the NAO, are discussed further in Annex IV.

1.4.2.1 Climate variability can influence trends over short periods

Natural variations in both weather and longer timescale phenomena can temporarily obscure or intensify any anthropogenic trends (e.g., Deser et al., 2012; Kay et al., 2015). These effects are more important on small spatial and temporal scales but can also occur on the global scale as well (see Cross-Chapter Box 3.1in Chapter 3).

Since AR5, many studies have examined the role of internal variability through the use of 'large ensembles'. Each such ensemble consists of many different simulations by a single climate model for the same time period and using the same radiative forcings. These simulations differ only in their phasing of the internal climate variations (also see Section 1.5.4.2). A set of illustrative examples using one such large ensemble (Maher et al., 2019) demonstrates how variability can influence trends on decadal timescales (Figure 1.13). The long-term anthropogenic trends in this set of climate indicators are clearly apparent when considering the ensemble as a whole (grey shading), and all the individual ensemble members have very similar trends for ocean heat content (OHC), which is a robust estimate of the total energy stored in the climate system (e.g., Palmer and McNeall, 2014). However, the individual ensemble members can exhibit very different decadal trends in global surface air temperature (GSAT), UK summer temperatures, and Arctic sea-ice variations. More specifically, for a representative 11-year period, both positive and negative trends can be found in all these surface indicators, even though the long-term trend is for increasing temperatures and decreasing sea ice. Periods in which the long-term trend is substantially obscured or intensified for more than 20 years are also visible in these regional examples, highlighting that observations are expected to exhibit short-term trends which are larger or smaller than the long-term trend or differ from the average projected trend from climate models, especially on continental spatial scales or smaller (see Cross Chapter Box 3.1 in Chapter 3). The actual observed trajectory can be considered as one realisation of many possible alternative worlds which experienced different weather, as also demonstrated by the construction of 'observation-based large ensembles' that are alternate possible realisations of historical observations, which retain the statistical properties of observed regional weather (e.g., McKinnon and Deser, 2018).

[START FIGURE 1.13 HERE]

Figure 1.13: Simulated changes in various climate indicators under historical and RCP4.5 scenarios using the MPI ESM Grand Ensemble. The grey shading shows the 5–95% range from the 100-member ensemble. The coloured lines represent individual example ensemble members, with linear trends for the 2011–2021 period indicated by the thin dashed lines. Changes in Ocean Heat Content (OHC) over the top 2000m represents the integrated signal of global warming (left). The top row shows surface air temperature-related indicators (annual GSAT change and UK summer temperatures) and the bottom row shows Arctic sea-ice related indicators (annual ice volume and September sea ice extent). For smaller regions and for shorter time period averages the variability increases and simulated short-term trends can temporarily obscure or intensify anthropogenic changes in climate. Data from Maher et al., (2019). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.13 HERE]

1.4.2.2 The emergence of the climate change signal

In the 1930s it was noted that temperatures were increasing at both local and global scales (Kincer, 1933; Callendar, 1938; Figure 1.8). At the time it was unclear whether the observed changes were part of a longer-

ACCEPTED VERSION SUBJECT TO FINAL EDITS

term trend or a natural fluctuation; the 'signal' had not yet clearly emerged from the 'noise' of natural variability. Numerous studies have since focused on the emergence of changes in temperature using instrumental observations (e.g., Madden and Ramanathan, 1980; Wigley and Jones, 1981; Mahlstein et al., 2011, 2012; Lehner and Stocker, 2015; Lehner et al., 2017) and paleo-temperature data (e.g., Abram et al., 2016).

Since the IPCC Third's Assessment report in 2001, the observed signal of climate change has been unequivocally detected at the global scale (see Section 1.3), and this signal is increasingly emerging from the noise of natural variability on smaller spatial scales and in a range of climate variables (see also FAQ1.2). In this Report emergence of a climate change signal or trend refers to when a change in climate (the 'signal') becomes larger than the amplitude of natural or internal variations (defining the 'noise'). This concept is often expressed as a 'signal to-noise' ratio (S/N) and emergence occurs at a defined threshold of this ratio (e.g. S/N > 1 or 2). Emergence can be estimated using observations and/or model simulations and can refer to changes relative to a historical or modern baseline (see Chapter 12, Section 12.5.2, Annex VII: Glossary). The concept can also be expressed in terms of time (the 'time of emergence'; Annex VII: Glossary) or in terms of a global warming level (Kirchmeier- Young et al., 2019; see Chapter 11, Section 11.2.5) and is also used to refer to a time when we can expect to see a response of mitigation activities that reduce emissions of greenhouse gases or enhance their sinks (emergence with respect to mitigation, see Chapter 4, Section 4.6.3.1). Whenever possible, emergence should be discussed in the context of a clearly defined level of S/N or other quantification, such as 'the signal has emerged at the level of S/N > 2', rather than as a simple binary statement. For an extended discussion, see Chapter 10 (Section 10.4.3).

Related to the concept of emergence is the detection of change (see Chapter 3). Detection of change is defined as the process of demonstrating that some aspect of the climate or a system affected by climate has changed in some defined statistical sense, often using spatially aggregating methods that try to maximise S/N, such as 'fingerprints' (e.g., Hegerl et al., 1996), without providing a reason for that change. An identified change is detected in observations if its likelihood of occurrence by chance due to internal variability alone is determined to be small, for example, <10% (Annex VII: Glossary).

An example of observed emergence in surface air temperatures is shown in Figure 1.14. Both the largest changes in temperature and the largest amplitude of year-to-year variations are observed in the Arctic, with lower latitudes showing less warming and smaller year-to-year variations. For the six example regions shown (Figure 1.14), the emergence of changes in temperature is more apparent in northern South America, East Asia and central Africa, than for northern North America or northern Europe. This pattern was predicted by Hansen et al. (1988) and noted in subsequent observations by Mahlstein et al. (2011) (see Chapter 10, Section 10.3.4.3, Chapter 12, Section 12.5.2). Overall, tropical regions show earlier emergence of temperature changes than at higher latitudes (*high confidence*).

Since AR5, the emergence of projected future changes has also been extensively examined, in variables including surface air temperature (Hawkins and Sutton, 2012; Kirtman et al., 2013; Tebaldi and Friedlingstein, 2013), ocean temperatures and salinity (Banks and Wood, 2002), mean precipitation (Giorgi and Bi, 2009; Maraun, 2013), drought (Orlowsky and Seneviratne, 2013), extremes (Diffenbaugh and Scherer, 2011; Fischer et al., 2014; King et al., 2015; Schleussner and Fyson, 2020), and regional sea level change (Lyu et al., 2014). The concept has also been applied to climate change impacts such as effects on crop growing regions (Rojas et al., 2019). In AR6, the emergence of oceanic signals such as regional sea level change and changes in water mass properties is assessed in Chapter 9 (Section 9.6.1.4), emergence of future regional changes is assed in Chapter 10 (Section 10.4.3), the emergence of extremes as a function of global warming levels is assessed in Chapter 11 (Section 11.2.5) and the emergence of climatic impact-drivers for AR6 regions and many climate variables is assessed in Chapter 12 (Section 12.5.2).

Although the magnitude of any change is important, regions which have a larger signal of change relative to the background variations will potentially face greater risks than other regions, as they will see unusual or novel climate conditions more quickly (Frame et al., 2017). As in Figure 1.14, the signal of temperature change is often smaller in tropical countries, but their lower amplitude of variability means they may experience the effects of climate change earlier than the mid-latitudes. In addition, these tropical countries

ACCEPTED VERSION SUBJECT TO FINAL EDITS

are often amongst the most exposed, due to large populations (Lehner and Stocker, 2015), and often more vulnerable (Harrington et al., 2016; Harrington and Otto, 2018; Russo et al., 2019); both of these factors increase the risk from climate-related impacts (Cross Chapter Box 1.3). The rate of change is also important for many hazards (e.g., Loarie et al., 2009). Providing more information about changes and variations on regional scales, and the associated attribution to particular causes (see Cross-Working Group Box: Attribution), is therefore important for adaptation planning.

[START FIGURE 1.14 HERE]

Figure 1.14: The observed emergence of changes in temperature. Top left: the total change in temperature estimated for 2020 relative to 1850–1900 (following Hawkins et al. 2020), showing the largest warming in the Arctic. Top right: the amplitude of estimated year-to-year variations in temperature. Middle left: the ratio of the observed total change in temperature and the amplitude of temperature variability (the 'signal-to-noise (S/N) ratio'), showing that the warming is most apparent in the tropical regions (also see FAQ1.2). Middle right: the global warming level at which the change in local temperature becomes larger than the local year-to-year variability. The bottom panels show time series of observed annual mean surface air temperatures over land in various example regions, as indicated as boxes in the top left panel. The 1 and 2 standard deviations of estimated year-to-year variations for that region are shown by the pink shaded bands. Observed temperature data from Berkeley Earth (Rohde and Hausfather, 2020). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.14 HERE]

1.4.3 Sources of uncertainty in climate simulations

When evaluating and analysing simulations of the physical climate system, several different sources of uncertainty need to be considered (e.g., Hawkins and Sutton, 2009; Lehner et al., 2020). Broadly, these sources are: uncertainties in radiative forcings (both those observed in the past and those projected for the future); uncertainty in the climate response to particular radiative forcings; internal and natural variations of the climate system (which may be somewhat predictable) and interactions among these sources of uncertainty.

Ensembles of climate simulations (see Section 1.5.4.2), such as those produced as part of the sixth phase of the Coupled Model Intercomparison Project (CMIP6), can be used to explore these different sources of uncertainty and estimate their magnitude. Relevant experiments with climate models include both historical simulations constrained by past radiative forcings and projections of future climate which are constrained by specified drivers, such as GHG concentrations, emissions, or radiative forcings. (The term 'prediction' is usually reserved for estimates of the future climate state which are also constrained by the observed initial conditions of the climate system, analogous to a weather forecast.)

1.4.3.1 Sources of uncertainty

Radiative forcing uncertainty

Future radiative forcing is uncertain due to as-yet-unknown societal choices that will determine future anthropogenic emissions; this is considered '*scenario uncertainty*'. The RCP and SSP scenarios, which form the basis for climate projections assessed in this report, are designed to span a plausible range of future pathways (see Section 1.6) and can be used to estimate the magnitude of scenario uncertainty, but the real world may also differ from any one of these example pathways.

Uncertainties also exist regarding past emissions and radiative forcings. These are especially important for simulations of paleoclimate time periods, such as the Pliocene, Last Glacial Maximum or the last millennium, but are also relevant for the CMIP historical simulations of the instrumental period since 1850. In particular, historical radiative forcings due to anthropogenic and natural aerosols are less well constrained

ACCEPTED VERSION SUBJECT TO FINAL EDITS

by observations than the greenhouse gas radiative forcings. There is also uncertainty in the size of large volcanic eruptions (and in the location for some that occurred before around 1850), and the amplitude of changes in solar activity, before satellite observations. The role of historical radiative forcing uncertainty was considered previously (Knutti et al., 2002; Forster et al., 2013) but, since AR5, specific simulations have been performed to examine this issue, particularly for the effects of uncertainty in anthropogenic aerosol radiative forcing (e.g., Jiménez-de-la-Cuesta and Mauritsen, 2019; Dittus et al., 2020).

Climate response uncertainty

Under any particular scenario (see Section 1.6.1), there is uncertainty in how the climate will respond to the specified emissions or radiative forcing combinations. A range of climate models is often used to estimate the range of uncertainty in our understanding of the key physical processes and to define the '*model response uncertainty*' (see Section 1.5.4 and Chapter 4, Section 4.2.5). However, this range does not necessarily represent the full '*climate response uncertainty'* in how the climate may respond to a particular radiative forcing or emissions scenario. This is because, for example, the climate models used in CMIP experiments have structural uncertainties not explored in a typical multi-model exercise (e.g., Murphy et al., 2004) and are not entirely independent of each other (Masson and Knutti, 2011; Abramowitz et al., 2019; see Section 1.5.4.8); there are small spatial-scale features which cannot be resolved; and long time-scale processes or tipping points are not fully represented. Section 1.4.4 discusses how some of these issues can still be considered in a risk assessment context. For some metrics, such as Equilibrium Climate Sensitivity (ECS), the CMIP6 model range is found to be broader than the *very likely* range assessed by combining multiple lines of evidence (see Chapter 4, Section 4.3.4 and Chapter 7, Section 7.5.6).

Natural and internal climate variations

Even without any anthropogenic radiative forcing, there would still be uncertainty in projecting future climate because of unpredictable natural factors such as variations in solar activity and volcanic eruptions. For projections of future climate, such as those presented in Chapter 4, the uncertainty in these factors is not normally considered. However, the potential effects on the climate of large volcanic eruptions (Cross-Chapter Box 4.1in Chapter 4, Zanchettin et al., 2016; Bethke et al., 2017) and large solar variations (Feulner and Rahmstorf, 2010; Maycock et al., 2015) are studied. On longer timescales, orbital effects and plate tectonics also play a role.

Further, even in the absence of any anthropogenic or natural changes in radiative forcing, Earth's climate fluctuates on timescales from days to decades or longer. These 'internal' variations, such as those associated with modes of variability (e.g., ENSO, Pacific Decadal Variability (PDV), or Atlantic Multi-decadal Variability (AMV) – see Annex IV) are unpredictable on timescales longer than a few years ahead and are a source of uncertainty for understanding how the climate might become in a particular decade, especially regionally. The increased use of 'large ensembles' of complex climate model simulations to sample this component of uncertainty is discussed above in Section 1.4.2.1 and further in Chapter 4.

Interactions between variability and radiative forcings

It is plausible that there are interactions between radiative forcings and climate variations, such as influences on the phasing or amplitude of internal or natural climate variability (Zanchettin, 2017). For example, the timing of volcanic eruptions may influence Atlantic multi-decadal variability (e.g., Otterå et al., 2010; Birkel et al., 2018) or ENSO (e.g., Maher et al., 2015; Khodri et al., 2017; Zuo et al., 2018), and anthropogenic aerosols may influence decadal modes of variability in the Pacific (e.g., Smith et al., 2016). In addition, melting of glaciers and ice caps due to anthropogenic influences has been speculated to increase volcanic activity (e.g., a specific example for Iceland is discussed in Swindles et al., 2018).

1.4.3.2 Uncertainty quantification

Not all of these listed sources of uncertainty are of the same type. For example, internal climate variations are an intrinsic uncertainty that can be estimated probabilistically, and could be more precisely quantified, but cannot usually be reduced. However, advances in decadal prediction offer the prospect of narrowing uncertainties in the trajectory of the climate for a few years ahead (e.g., Meehl et al., 2014; Yeager and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Robson, 2017; Chapter 4, Section 4.2.3).

Other sources of uncertainty, such as model response uncertainty, can in principle be reduced, but are not amenable to a frequency-based interpretation of probability, and Bayesian methods to quantify the uncertainty have been considered instead (e.g., Tebaldi, 2004; Rougier, 2007; Sexton et al., 2012). The scenario uncertainty component is distinct from other uncertainties, given that future anthropogenic emissions can be considered as the outcome of a set of societal choices (see Section 1.6.1).

For climate model projections it is possible to approximately quantify the relative amplitude of various sources of uncertainty (e.g., Hawkins and Sutton, 2009; Lehner et al., 2020). A range of different climate models are used to estimate the model response uncertainty to a particular emissions pathway, and multiple pathways are used to estimate the scenario uncertainty. The unforced component of internal variability can be estimated from individual ensemble members of the same climate model (e.g., Deser et al., 2012; Maher et al., 2019; Section 1.5.4.8).

Figure 1.15 illustrates the relative size of these different uncertainty components using a 'cascade of uncertainty' (Wilby and Dessai, 2010), with examples shown for global mean temperature, northern South American annual temperatures and East Asian summer precipitation changes. For global mean temperature, the role of internal variability is small, and the total uncertainty is dominated by emissions scenario and model response uncertainties. Note that there is considerable overlap between individual simulations for different emissions scenarios even for the mid-term (2041–2060). For example, the slowest-warming simulation for SSP5-8.5 produces less mid-term warming than the fastest-warming simulation for SSP1-1.9. For the long-term, emissions scenario uncertainty becomes dominant.

The relative uncertainty due to internal variability and model uncertainty increases for smaller spatial scales. In the regional example shown for changes in temperature, the same scenario and model combination has produced two simulations which differ by 1°C in their projected 2081–2100 averages due solely to internal climate variability. For regional precipitation changes, emissions scenario uncertainty is often small relative to model response uncertainty. In the example shown, the SSPs overlap considerably, but SSP1-1.9 shows the largest precipitation change in the near-term even though global mean temperature warms the least; this is due to differences between regional aerosol emissions projected in this and other scenarios (Wilcox et al., 2020). These cascades of uncertainty would branch out further if applying the projections to derive estimates of changes in hazard (e.g., Wilby and Dessai, 2010; Halsnæs and Kaspersen, 2018; Hattermann et al., 2018).

[START FIGURE 1.15 HERE]

Figure 1.15: The 'cascade of uncertainties' in CMIP6 projections. Changes in GSAT (left), northern South America (region NSA) temperature change (middle), and East Asia (region EAS) summer (JJA) precipitation change (right) are shown for two time periods (2041–2060, top, and 2081–2100, bottom). The SSP-radiative forcing combination is indicated at the top of each cascade at the value of the multi-model mean for each scenario. This branches downwards to show the ensemble mean for each model, and further branches into the individual ensemble members, although often only a single member is available. These diagrams highlight the relative importance of different sources of uncertainty in climate projections, which varies for different time periods, regions and climate variables. See Section 1.4.5 for the definition of the regions used. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.15 HERE]

1.4.4 Considering an uncertain future

Since AR5 there have been developments in how to consider and describe future climate outcomes which are considered possible but *very unlikely,* highly uncertain, or potentially surprising. To examine such futures there is a need to move beyond the usual *'likely'* or *'very likely'* assessed ranges and consider low-likelihood

ACCEPTED VERSION SUBJECT TO FINAL EDITS

outcomes, especially those that would result in significant impacts if they occurred (e.g., Sutton, 2018; Sillmann et al., 2021). This section briefly outlines some of the different approaches used in the AR6 WGI.

1.4.4.1 Low-likelihood outcomes

In the AR6, certain low-likelihood outcomes are described and assessed because they may be associated with high levels of risk and the greatest risks may not be associated with the most expected outcome. The aim of assessing these possible futures is to better inform risk assessment and decision making. Two types are considered: (1) low-likelihood high warming (LLHW) scenarios, which describe the climate in a world with very high climate sensitivity, and (2) low-likelihood high impact (LLHI) events that have a low likelihood of occurring, but would cause large potential impacts on society or ecosystems.

An illustrative example of how low-likelihood outcomes can produce significant additional risks is shown in Figure 1.16. The Reasons for Concern (RFCs) produced by the IPCC AR5 WGII define the additional risks due to climate change at different global warming levels. These have been combined with Chapter 4 assessments of projected global temperature for different emissions scenarios (SSPs; see Section 1.6), and Chapter 7 assessments about ECS. For example, even following a medium emissions scenario could result in high levels of additional risk if ECS is at the upper end of the *very likely* range. However, not all possible low-likelihood outcomes relate to ECS, and AR6 considers these issues in more detail than previous IPCC assessment reports (see Table 1.1 and below for some examples).

[START FIGURE 1.16 HERE]

Figure 1.16: Illustrating concepts of low-likelihood scenarios. Left: schematic likelihood distribution consistent with the IPCC AR6 assessments that equilibrium climate sensitivity (ECS) is *likely* in the range 2.5 to 4.0°C, and *very likely* between 2.0 and 5.0°C (Chapter 7). ECS values outside the assessed *very likely* range are designated low-likelihood scenarios in this example (light grey). Middle and right columns: additional risks due to climate change for 2020–2090 using the Reasons For Concern (RFCs, see IPCC, 2014), specifically RFC1 describing the risks to unique and threatened systems and RFC3 describing risks from the distribution of impacts (O'Neill et al., 2017b; Zommers et al., 2020). The projected changes of GSAT used are the 95%, median and 5% assessed ranges from Chapter 4 for each SSP (top, middle and bottom); these are designated High ECS, Mid-range ECS and Low ECS respectively. The burning-ember risk spectrum is usually associated with levels of committed GSAT change; instead, this illustration associates the risk spectrum with the GSAT reached in each year from 2020 to 2090. Note that this illustration does not include the vulnerability aspect of each SSP scenario. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.16 HERE]

1.4.4.2 Storylines

As societies are increasingly experiencing the impacts of climate change related events, the climate science community is developing climate information tailored for particular regions and sectors. There is a growing focus on explaining and exploring complex physical chains of events or on predicting climate under various future socio-economic developments. Since AR5, 'storylines' or 'narratives' approaches have been used to better inform risk assessment and decision making, to assist understanding of regional processes, and represent and communicate climate projection uncertainties more clearly. The aim is to help build a cohesive overall picture of potential climate change pathways that moves beyond the presentation of data and figures (Annex VII: Glossary; Fløttum and Gjerstad, 2017; Moezzi et al., 2017; Dessai et al., 2018; Shepherd et al., 2018b).

In the broader IPCC context, the term 'scenario storyline' refers to a narrative description of one or more scenarios, highlighting their main characteristics, relationships between key driving forces and the dynamics

ACCEPTED VERSION SUBJECT TO FINAL EDITS

of their evolution (for example, short-lived climate forcers emissions assessed in Chapter 6 are driven by 'scenario storylines', see Section 1.6). WGI is mainly concerned with 'physical climate storylines'. These are self-consistent and possible unfolding of a physical trajectory of the climate system, or a weather or climate event, on timescales from hours to multiple decades (Shepherd et al., 2018b). This approach can be used to constrain projected changes or specific events on specified explanatory elements such as projected changes of large-scale indicators (Chapter 10, Box 10.2). For example, Hazeleger et al. (2015) suggested using 'tales of future weather', blending numerical weather prediction with a climate projection to illustrate the potential behaviour of future high-impact events (also see Hegdahl et al. 2020). Several studies describe how possible large changes in atmospheric circulation would affect regional precipitation and other climate variables, and discuss the various climate drivers which could cause such a circulation response (James et al., 2015; Zappa and Shepherd, 2017; Mindlin et al., 2020). Physical climate storylines can also help frame the causal factors of extreme weather events (Shepherd, 2016) and then be linked to event attribution (Chapter 11, Section 11.2.2; Cross Working Group Box: Attribution).

Storyline approaches can be used to communicate and contextualise climate change information in the context of risk for policymakers and practitioners (e.g., de Bruijn et al., 2016; Dessai et al., 2018; Scott et al., 2018; Jack et al., 2020; Chapter 10, Box 10.2). They can also help in assessing risks associated with LLHI events (Weitzman, 2011; Sutton, 2018), because they consider the 'physically self-consistent unfolding of past events, or of plausible future events or pathways' (Shepherd et al., 2018b), which would be masked in a probabilistic approach. These aspects are important as the greatest risk need not be associated with the highest-likelihood outcome, and in fact will often be associated with low-likelihood outcomes. The storyline approach can also acknowledge that climate-relevant decisions in a risk-oriented framing will rarely be taken on the basis of physical climate change alone; instead, such decisions will normally take into account socio-economic factors as well (Shepherd, 2019).

In the AR6 WGI Assessment Report, these different storyline approaches are used in several places (see Table 1.1). Chapter 4 uses a storyline approach to assess the upper tail of the distribution of global warming levels (the storylines of high global warming levels) and their manifestation in global patterns of temperature and precipitation changes. Chapter 9 uses a storyline approach to examine the potential for, and early warning signals of, a high-end sea-level scenario, in the context of deep uncertainty related to our current understanding the physical processes that contribute to long-term sea-level rise. Chapter 10 assesses the use of physical climate storylines and narratives as a way to explore uncertainties in regional climate projections, and to link to the specific risk and decision context relevant to a user, for developing integrated and context-relevant regional climate change information. Chapter 11 uses the term storyline in the framework of extreme event attribution. Chapter 12 assesses the use of a storylines approach with narrative elements for communicating climate (change) information in the context of climate services (Cross-Chapter Box 12.2 in Chapter 12).

[START CROSS-CHAPTER BOX 1.3 HERE]

Cross-Chapter Box 1.3: Risk framing in IPCC AR6

Contributing Authors: Andy Reisinger (New Zealand), Maisa Rojas (Chile), Maarten van Aalst (Netherlands), Aïda Diongue-Niang (Senegal), Mathias Garschagen (Germany), Mark Howden (Australia), Margot Hurlbert (Canada), Katie Mach (USA), Sawsan Mustafa (Sudan), Brian O'Neill (USA), Roque Pedace (Argentina), Jana Sillmann (Norway), Carolina Vera (Argentina), David Viner (UK).

The IPCC SREX presented a framework for assessing risks from climate change, linking hazards (due to changes in climate) with exposure and vulnerability (Cardona et al., 2012). This framework was further developed by AR5 WGII (IPCC, 2014b), while AR5 WGI focussed only on the hazard component of risk. As part of AR6, a cross-Working Group process expanded and refined the concept of risk to allow for a consistent risk framing to be used across the three IPCC working groups (IPCC, 2019b; Box 2 in Abram et al., 2019; Reisinger et al., 2020).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

In this revised definition, risk is the 'potential for adverse consequences for human or ecological systems, recognising the diversity of values and objectives associated with such systems. In the context of climate change, risks can arise not only from **impacts of climate change**, but also from potential human **responses to climate change**. Relevant adverse consequences include those on lives, livelihoods, health and wellbeing, economic, social and cultural assets and investments, infrastructure, services (including ecosystem services), ecosystems and species.

In the context of climate change impacts, risks result from dynamic interactions between climate-related hazards with the exposure and vulnerability of the affected human or ecological system to hazards. Hazards, exposure and vulnerability may each be subject to uncertainty in terms of magnitude and likelihood of occurrence, and each may change over time and space due to socio-economic changes and human decision-making.

In the context of climate change responses, risks result from the potential for such responses not achieving the intended objective(s), or from potential trade-offs with, or negative side-effects on, other societal objectives, such as the Sustainable Development Goals. Risks can arise for example from uncertainty in implementation, effectiveness or outcomes of climate policy, climate-related investments, technology development or adoption, and system transitions'.

The following concepts are also relevant for the definition of risk (see Annex VII: Glossary):

Exposure: The presence of people, livelihoods, species or ecosystems, environmental functions, services, and resources, infrastructure, or economic, social, or cultural assets in places and settings that could be adversely affected.

Vulnerability: The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts and elements including sensitivity or susceptibility to harm and lack of capacity to cope and adapt.

Hazard: The potential occurrence of a natural or human-induced physical event or trend that may cause loss of life, injury, or other health impacts, as well as damage and loss to property, infrastructure, livelihoods, service provision, ecosystems and environmental resources.

Impacts: The consequences of realised risks on natural and human systems, where risks result from the interactions of climate-related hazards (including extreme weather and climate events), exposure, and vulnerability. Impacts generally refer to effects on lives, livelihoods, health and wellbeing, ecosystems and species, economic, social and cultural assets, services (including ecosystem services), and infrastructure. Impacts may be referred to as consequences or outcomes, and can be adverse or beneficial.

Risk in AR6 WGI

The revised risk framing clarifies the role and contribution of WGI to risk assessment. Risk in IPCC terminology applies only to human or ecological systems, not to physical systems on their own.

Climatic impact-drivers: CIDs are physical climate system conditions (e.g., means, extremes, events) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions.

In AR6, WGI uses the term 'climatic impact-drivers' (CIDs) to describe changes in physical systems rather than 'hazards', because the term hazard already assumes an adverse consequence. The terminology of 'climatic impact-driver' therefore allows WGI to provide a more value-neutral characterisation of climatic changes that may be relevant for understanding potential impacts, without pre-judging whether specific climatic changes necessarily lead to adverse consequences, as some could also result in beneficial outcomes depending on the specific system and associated values. Chapter 12 and the Atlas assess and provide information on climatic impact-drivers for different regions and sectors to support and link to WGII

ACCEPTED VERSION SUBJECT TO FINAL EDITS

assessment of the impacts and risks (or opportunities) related to the changes in the climatic impact-drivers. Although CIDs can lead to adverse or beneficial outcomes, focus is given to CIDs connected to hazards, and hence inform risk.

'Extremes' are a category of CID, corresponding to unusual events with respect to the range of observed values of the variable. Chapter 11 assesses changes in weather and climate extremes, their attribution and future projections.

As examples of the use of this terminology, the term 'flood risk' should not be used if it only describes changes in the frequency and intensity of flood events (a hazard); the risk from flooding to human and ecological systems is caused by the flood hazard, the exposure of the system affected (e.g., topography, human settlements or infrastructure in the area potentially affected by flooding) and the vulnerability of the system (e.g., design and maintenance of infrastructure, existence of early warning systems). As another example, climate-related risk to food security can arise from both potential climate change impacts and responses to climate change and can be exacerbated by other stressors. Drivers for risks related to climate change impacts include climate hazards (e.g., drought, temperature extremes, humidity), mediated by other climatic impact-drivers (e.g., increased CO_2 fertilisation of certain types of crops may help increase yields), the potential for indirect climate-related impacts (e.g., pest outbreaks triggered by ecosystem responses to weather patterns), exposure of people (e.g., how many people depend on a particular crop) and vulnerability or adaptability (how able are affected people to substitute other sources of food, which may be related to financial access and markets).

Information provided by WGI may or may not be relevant to understand risks related to climate change responses. For example, the risk to a company arising from emissions pricing, or the societal risk from reliance on an unproven mitigation technology, are not directly dependent on actual or projected changes in climate but arise largely from human choices. However, WGI climate information may be relevant to understand the potential for maladaptation, such as the potential for specific adaptation responses not achieving the desired outcome or having negative side-effects. For example, WGI information about the range of sea level rise can help inform understanding of whether coastal protection, accommodation, or retreat would be the most effective risk management strategy in a particular context.

From a WGI perspective also relevant for risk assessment are low-likelihood high impact events and the concept of deep uncertainty.

Low-likelihood, high-impact events: (LLHI) 'These are events whose probability of occurrence is low but whose potential impacts on society and ecosystems are high. To better inform risk assessment and decision making, such low likelihood outcomes are described as they may be associated with very high levels of risk and because the greatest risks might not be associated with the most expected outcome.

The AR6 WGI report provides more detailed information about these types of events compared to the AR5 (see Table 1.1, Section 1.4.4).

Recognising the need for assessing and managing risk in situations of high uncertainty, the SROCC advanced the treatment of situations with deep uncertainty (IPCC, 2019b; Box 5 in Abram et al., 2019); Section 1.2.3). A situation of deep uncertainty exists when experts or stakeholders do not know or cannot agree on: (1) appropriate conceptual models that describe relationships among key driving forces in a system; (2) the probability distributions used to represent uncertainty about key variables and parameters; and/or (3) how to weigh and value desirable alternative outcomes (Abram et al., 2019). The concept of deep uncertainty can complement the IPCC calibrated language and thereby broaden the communication of risk.

[END CROSS-CHAPTER BOX 1.3 HERE]

1.4.4.3 Abrupt change, tipping points and surprises

ACCEPTED VERSION SUBJECT TO FINAL EDITS

An *abrupt change* is defined in this report as a change that takes place substantially faster than the rate of change in the recent history of the affected component of a system (see Annex VII: Glossary). In some cases, abrupt change occurs because the system state actually becomes unstable, such that the subsequent rate of change is independent of the forcing. We refer to this class of abrupt change as a *tipping point,* defined as a critical threshold beyond which a system reorganizes, often abruptly and/or irreversibly (Lenton et al., 2008); Annex VII: Glossary). Some of the abrupt climate changes and climate tipping points discussed in this report could have severe local climate responses, such as extreme temperature, droughts, forest fires, ice sheet loss and collapse of the thermohaline circulation (see Chapter 4, Section 4.7.2, Chapter 5, Section 5.4.9, Chapter 8, Section 8.6 and Chapter 9, Section 9.2.3).

There is evidence of abrupt change in Earth's history, and some of these events have been interpreted as tipping points (Dakos et al., 2008) . Some of these are associated with significant changes in the global climate, such as deglaciations in the Quaternary (past 2.5 million years) and rapid warming at the Palaeocene-Eocene Thermal Maximum (around 55.5 million years ago) (Bowen et al., 2015; Hollis et al., 2019). Such events changed the planetary climate for tens to hundreds of thousands of years, but at a rate that is actually much slower than projected anthropogenic climate change over this century, even in the absence of tipping points.

Such paleoclimate evidence has even fuelled concerns that anthropogenic GHGs could tip the global climate into a permanent hot state (Steffen et al., 2018). However, there is no evidence of such non-linear responses at the global scale in climate projections for the next century, which indicate a near-linear dependence of global temperature on cumulative GHG emissions (Section 1.3.5, Chapter 5, Section 5.5 and Chapter 7, Section 7.4.3.1). At the regional scale, abrupt changes and tipping points, such as Amazon forest dieback and permafrost collapse, have occurred in projections with Earth System Models (Drijfhout et al., 2015; Bathiany et al., 2020; Chapter 4, Section 4.7.3). In such simulations, tipping points occur in narrow regions of parameter space (e.g., CO_2 concentration or temperature increase), and for specific climate background states. This makes them difficult to predict using ESMs relying on parmeterizations of known processes. In some cases, it is possible to detect forthcoming tipping points through time-series analysis that identifies increased sensitivity to perturbations as the tipping point is approached (e.g., 'critical slowing-down', Scheffer et al., 2012).

Some suggested climate tipping points prompt transitions from one steady state to another (see Figure 1.17). Transitions can be prompted by perturbations such as climate extremes which force the system outside of its current well of attraction in the stability landscape; this is called noise-induced tipping (Ashwin et al., 2012; Figure 1.17, panels a/b). For example, the tropical forest dieback seen in some ESM projections is accelerated by longer and more frequent droughts over tropical land (Good et al., 2013).

Alternatively, transitions from one state to another can occur if a critical threshold is exceeded; this is called bifurcation tipping (Ashwin et al., 2012; Figure 1.17, panels c/d). The new state is defined as *irreversible* on a given timescale if the recovery from this state takes substantially longer than the timescale of interest, which is decades to centuries for the projections presented in this report. A well-known example is the modelled irreversibility of the ocean's thermohaline circulation in response to North Atlantic changes such as freshwater input from rainfall and ice-sheet melt (Rahmstorf et al., 2005; Alkhayuon et al., 2019), which is assessed in detail in Chapter 9, Section 9.2.3.

The tipping point concept is most commonly framed for systems in which the forcing changes relatively slowly. However, this is not the case for most scenarios of anthropogenic forcing projected for the 21st century. Systems with inertia lag behind rapidly-increasing forcing, which can lead to the failure of early warning signals or even the possibility of temporarily overshooting a bifurcation point without provoking tipping (Ritchie et al., 2019).

[START FIGURE 1.17 HERE]

Figure 1.17: Illustration of two types of tipping points: noise-induced (panels a, b) and bifurcation (panels c, d).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(a), (c) example time-series (coloured lines) through the tipping point with black solid lines indicating stable climate states (e.g., low or high rainfall) and dashed lines represent the boundary between stable states. (b), (d) stability landscapes provide an intuitive understanding for the different types of tipping point. The valleys represent different climate states the system can occupy, with hill tops separating the stable states. The resilience of a climate state is implied by the depth of the valley. The current state of the system is represented by a ball. Both scenarios assume that the ball starts in the left-hand valley (black dashed lines) and then through different mechanisms dependent on the type of tipping transitions to the right valley (coloured lines). Noise-induced tipping events, for instance drought events causing sudden dieback of the Amazonian rainforest, develop from fluctuations within the system. The stability landscape in this scenario remains fixed and stationary. A series of perturbations in the same direction or one large perturbation are required to force the system over the hill top and into the alternative stable state. Bifurcation tipping events, such as a collapse of the thermohaline circulation in the Atlantic Ocean under climate change, occur when a critical level in the forcing is reached. Here the stability landscape is subjected to a change in shape. Under gradual anthropogenic forcing the left valley begins to shallow and eventually vanishes at the tipping point, forcing the system to transition to the right-hand valley.

[END FIGURE 1.17 HERE]

Surprises are a class of risk that can be defined as low-likelihood but well-understood events, and events that cannot be predicted with current understanding. The risk from such surprises can be accounted for in risk assessments (Parker and Risbey, 2015). Examples relevant to climate science include: a series of major volcanic eruptions or a nuclear war, either of which would cause substantial planetary cooling (Robock et al., 2007; Mills et al., 2014); significant 21st century sea level rise due to marine ice sheet instability (MISI, Chapter 9, Box 9.4); the potential for collapse of the stratocumulus cloud decks (Schneider et al., 2019) or other substantial changes in climate feedbacks (see Chapter 7, Section 7.4); and unexpected biological epidemics among humans or other species, such as the COVID-19 pandemic (Forster et al., 2020; Le Quéré et al., 2020; see Cross-Chapter Box 6.1 in Chapter 6). The discovery of the ozone hole was also a surprise even though some of the relevant atmospheric chemistry was known at the time. The term 'unknown unknowns' (Parker and Risbey, 2015) is also sometimes used in this context to refer to events that cannot be anticipated with present knowledge or were of an unanticipated nature before they occurred.

[START CROSS-WORKING GROUP BOX: ATTRIBUTION HERE]

Cross-Working Group Box: Attribution

Contributing Authors: Wolfgang Cramer (France/Germany), Pandora Hope (Australia), Maarten van Aalst (Netherlands), Greg Flato (Canada), Katja Frieler (Germany), Nathan Gillett (Canada/UK), Christian Huggel (Switzerland), Jan Minx (Germany), Friederike Otto (UK/Germany), Camille Parmesan (France/UK/USA), Joeri Rogelj (UK/Belgium), Maisa Rojas (Chile), Sonia I. Seneviratne (Switzerland), Aimee Slangen (Netherlands), Daithi Stone (New Zealand), Laurent Terray (France), Robert Vautard (France), Xuebin Zhang (Canada)

Introduction

Changes in the climate system are becoming increasingly apparent, as are the climate-related impacts on natural and human systems. Attribution is the process of evaluating the contribution of one or more causal factors to such observed changes or events. Typical questions addressed by the IPCC are for example: 'To what degree is an observed change in global temperature induced by anthropogenic greenhouse gas and aerosol concentration changes or influenced by natural variability?' or 'What is the contribution of climate change to observed changes in crop yields that are also influenced by changes in agricultural management?' Changes in the occurrence and intensity of extreme events can also be attributed, addressing questions such as: 'Have human greenhouse gas emissions increased the likelihood or intensity of an observed heat wave?'

This Cross-Working Group Box briefly describes why attribution studies are important. It also describes

ACCEPTED VERSION SUBJECT TO FINAL EDITS

some new developments in the methods used and provides recommendations for interpretation.

Attribution studies serve to evaluate and communicate linkages associated with climate change, for example: between the human-induced increase in greenhouse gas concentrations and the observed increase in air temperature or extreme weather events (WGI Chapter 3, 10, 11); or between observed changes in climate and changing species distributions and food production (WGII Chapters 2 and others, summarised in Chapter 16) (e.g., Verschuur et al., 2021); or between climate change mitigation policies and atmospheric greenhouse gas concentrations (WGI Chapter 5; WGIII Chapter 14). As such, they support numerous statements made by the IPCC (IPCC, 2013b, 2014b; WGI Chapter 1, Section 1.3, Appendix 1A).

Attribution assessments can also serve to monitor mitigation and assess the efficacy of applied climate protection policies (e.g., Nauels et al., 2019; Banerjee et al., 2020; WGI Chapter 4, Section 4.6.3), inform and constrain projections (Gillett et al., 2021; Ribes et al., 2021; WGI Chapter 4, Section 4.2.3) or inform the loss and damages estimates and potential climate litigation cases by estimating the costs of climate change (Huggel et al., 2015; Marjanac et al., 2017; Frame et al., 2020). These findings can thus inform mitigation decisions as well as risk management and adaptation planning (e.g., CDKN, 2017).

Steps towards an attribution assessment

The unambiguous framing of what is being attributed to what is a crucial first step for an assessment (Easterling et al., 2016; Hansen et al., 2016; Stone et al., 2021), followed by the identification of the possible and plausible drivers of change and the development of a hypothesis or theory for the linkage (see Cross-Working Group Box: Attribution, Figure 1). The next step is to clearly define the indicators of the observed change or event and note the quality of the observations. There has been significant progress in the compilation of fragmented and distributed observational data, broadening and deepening the data basis for attribution research (e.g., Poloczanska et al., 2013; Ray et al., 2015; Cohen et al., 2018; WGI Chapter 1, Section 1.5). The quality of the observational record of drivers should also be considered (e.g., volcanic eruptions: WGI Chapter 2, section 2.2.2). Impacted systems also change in the absence of climate change; this baseline and its associated modifiers such as agricultural developments or population growth need to be considered, alongside the exposure and vulnerability of people depending on these systems.

There are many attribution approaches, and several methods are detailed below. In physical and biological systems, attribution often builds on the understanding of the mechanisms behind the observed changes and numerical models are used, while in human systems other methods of evidence-building are employed. Confidence in the attribution can be increased if more than one approach is used and the model is evaluated as fit-for-purpose (Hegerl et al., 2010; Vautard et al., 2019; Otto et al., 2020; Philip et al., 2020) (WGI Chapter 1, Section 1.5). Finally, appropriate communication of the attribution assessment and the accompanying confidence in the result (e.g., Lewis et al., 2019).

Attribution methods

Attribution of changes in atmospheric greenhouse gas concentrations to anthropogenic activity

AR6 WGI Chapter 5 presents multiple lines of evidence that unequivocally establish the dominant role of human activities in the growth of atmospheric CO_2, including through analysing changes in atmospheric carbon isotope ratios and the atmospheric O_2-N_2 ratio (WGI Chapter 5, Section 5.2.1.1). Decomposition approaches can be used to attribute emissions underlying those changes to various drivers such as population, energy efficiency, consumption or carbon intensity (Hoekstra and van den Bergh, 2003; Raupach et al., 2007; Rosa and Dietz, 2012). Combined with attribution of their climate outcomes, the attribution of the sources of greenhouse gas emissions can inform the attribution of anthropogenic climate change to specific countries or actors (Matthews, 2016; Otto et al., 2017; Skeie et al., 2017; Nauels et al., 2019), and in turn inform discussions on fairness and burden sharing (WGIII Chapter 14).

Attribution of observed climate change to anthropogenic forcing

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Changes in large-scale climate variables (e.g., global mean temperature) have been reliably attributed to anthropogenic and natural forcings (e.g., Hegerl et al., 2010; Bindoff et al., 2013; WGI Chapter 1, Section 1.3.4). The most established method is to identify the 'fingerprint' of the expected space-time response to a particular climate forcing agent such as the concentration of anthropogenically induced greenhouse gases or aerosols, or natural variation of solar radiation. This technique disentangles the contribution of individual forcing agents to an observed change (e.g., Gillett et al., 2021). New statistical approaches have been applied to better account for internal climate variability and the uncertainties in models and observations (e.g., Naveau et al., 2018; Santer et al., 2019) (WGI, Chapter 3 Section 3.2). There are many other approaches, for example, global mean sea-level change has been attributed to anthropogenic climate forcing by attributing the individual contributions from, for example, glacier melt or thermal expansion, while also examining which aspects of the observed change are inconsistent with internal variability (WGI Chapter 3, Section 3.5.2 and WGI Chapter 9, Section 9.6.1.4).

Specific regional conditions and responses may simplify or complicate attribution on those scales. For example, some human forcings, such as regional land use change or aerosols, may enhance or reduce regional signals of change (Lejeune et al., 2018; Undorf et al., 2018; Boé et al., 2020; Thiery et al., 2020; see also WGI Chapter 10, Section 10.4.2; WGI Chapter 11, Sections 11.1.6 and 11.2.2. In general, regional climate variations are larger than the global mean climate, adding additional uncertainty to attribution (e.g., in regional sea-level change, WGI Chapter 9, Section 9.6.1). These statistical limitations may be reduced by 'process-based attribution', focusing on the physical processes known to influence the response to external forcing and internal variability (WGI Chapter 10, Section 10.4.2).

Attribution of weather and climate events to anthropogenic forcing

New methods have emerged since AR5 to attribute the change in likelihood or characteristics of weather or climate events or classes of events to underlying drivers (National Academies of Sciences Engineering and Medicine, 2016; Stott et al., 2016; Jézéquel et al., 2018; Wehner et al., 2018; Wang et al., 2020; WGI Chapter 10, Section 10.4.1; WG1 Chapter 11, Section 11.2.2). Typically, historical changes, simulated under observed forcings, are compared to a counterfactual climate simulated in the absence of anthropogenic forcing. Another approach examines facets of the weather and thermodynamic status of an event through process-based attribution (Hauser et al., 2016; Shepherd et al., 2018b; Grose et al., 2019; WGI Chapter 10 Section 10.4.1 and Chapter 11). Events where attributable human influences have been found include hot and cold temperature extremes (including some with wide-spread impacts), heavy precipitation, and certain types of droughts and tropical cyclones (e.g., Vogel et al., 2019; Herring et al., 2021; AR6 WGI Chapter 11, Section 11.9). Event attribution techniques have sometimes been extended to 'end-to-end' assessments from climate forcing to the impacts of events on natural or human systems (Otto, 2017, examples in WGII Table 16.1, SI of WGII Chapter 16, Section 16.2).

Attribution of observed changes in natural or human systems to climate-related drivers

The attribution of observed changes to climate-related drivers across a diverse set of sectors, regions and systems is part of each chapter in the WGII contribution to the AR6 and is synthesised in WGII Chapter 16 (Section 16.2). The number of attribution studies on climate change impacts has grown substantially since AR5, generally leading to higher confidence levels in attributing the causes of specific impacts. New studies include the attribution of changes in socio-economic indicators such as economic damages due to river floods (e.g., Schaller et al., 2016; Sauer et al., 2021), the occurrence of heat related human mortality (e.g., Sera et al., 2020, Vicedo-Cabrera et al., 2018;) or economic inequality (e.g., Diffenbaugh and Burke, 2019).

Impact attribution covers a diverse set of qualitative and quantitative approaches, building on experimental approaches, observations from remote sensing, long-term in situ observations, and monitoring efforts, teamed with local knowledge, process understanding and empirical or dynamical modelling (WGII Chapter 16, Section 16.2; Stone et al., 2013; Cramer et al., 2014). The attribution of a change in a natural or human system (e.g., wild species, natural ecosystems, crop yields, economic development, infrastructure or human health) to changes in climate-related systems (i.e., climate, and ocean acidification, permafrost thawing or

ACCEPTED VERSION SUBJECT TO FINAL EDITS

sea-level rise) requires accounting for other potential drivers of change, such as technological and economic changes in agriculture affecting crop production (Hochman et al., 2017; Butler et al., 2018), changes in human population patterns and vulnerability affecting flood or wildfire induced damages (Huggel et al., 2015; Sauer et al., 2021), or habitat loss driving declines in wild species (IPBES, 2019). These drivers are accounted for by estimating a baseline condition that would exist in the absence of climate change. The baseline might be stationary and be approximated by observations from the past, or it may change over time and be simulated by statistical or process-based impact models (Cramer et al. 2014, WGII Chapter 16, Section 16.2). Assessment of multiple independent lines of evidence, taken together, can provide rigorous attribution when more quantitative approaches are not available (Parmesan et al., 2013). These include paleodata, physiological and ecological experiments, natural 'experiments' from very long-term datasets indicating consistent responses to the same climate trend/event, and 'fingerprints' in species' responses that are uniquely expected from climate change (e.g. poleward range boundaries expanding and equatorial range boundaries contracting in a coherent pattern world-wide, Parmesan and Yohe, 2003). Meta-analyses of species/ecosystem responses, when conducted with wide geographic coverage, also provide a globally coherent signal of climate change at an appropriate scale for attribution to anthropogenic climate change (Parmesan and Yohe, 2003; Parmesan et al., 2013).

Impact attribution does not always involve attribution to anthropogenic climate forcing. However, a growing number of studies include this aspect (e.g., Frame et al., 2020 for the attribution of damages induced by hurricane Harvey; or Diffenbaugh and Burke, 2019 for the attribution of economic inequality between countries; or Schaller et al., 2016 for flood damages).

[START CROSS-WORKING GROUP BOX: ATTRIBUTION, FIGURE 1 HERE]

Cross-Working Group Box: Attribution, Figure 1: Schematic of the steps to develop an attribution assessment, and the purposes of such assessments. Methods and systems used to test the attribution hypothesis or theory include model-based fingerprinting, other model-based methods, evidence-based fingerprinting, process-based approaches, empirical or decomposition methods and the use of multiple lines of evidence. Many of the methods are based on the comparison of the observed state of a system to a hypothetical counterfactual world that does not include the driver of interest to help estimate the causes of the observed response.

[END CROSS-WORKING GROUP BOX: ATTRIBUTION HERE]

1.4.5 Climate regions used in AR6

1.4.5.1 Defining climate regions

AR5 assessed regional scale detection and attribution and assessed key regional climate phenomena and their relevance for future regional climate projections. This report shows that past and future climate changes and extreme weather events can be substantial on local and regional scales (Chapters 8–12, Atlas), where they may differ considerably from global trends, not only in intensity but even in sign (e.g., Fischer et al., 2013).

Although the evolution of global climate trends emerges as the net result of regional phenomena, average or aggregate estimates often do not reflect the intensity, variability, and complexity of regional climate changes (Stammer et al., 2018; Shepherd, 2019). A fundamental aspect of the study of regional climate changes is the definition of characteristic climate zones, clusters or regions, across which the emergent climate change signal can be properly analysed and projected (see Atlas). Suitable sizes and shapes of such zones strongly

ACCEPTED VERSION SUBJECT TO FINAL EDITS

depend not only on the climate variable and process of interest, but also on relevant multiscale feedbacks.

There are several approaches to the classification of climate regions. When climate observation data was sparse and limited, the aggregation of climate variables was implicitly achieved through the consideration of biomes, giving rise to the traditional vegetation-based classification of Köppen (1936). In the last decades, the substantial increases in climate observations, climate modelling, and data processing capabilities have allowed new approaches to climate classification, e.g., through interpolation of aggregated global data from thousands of stations (Peel et al., 2007; Belda et al., 2014; Beck et al., 2018a) or through data-driven approaches applied to delineate ecoregions that behave in a coherent manner in response to climate variability (Papagiannopoulou et al., 2018). Experience shows that each method has strengths and weaknesses through trade-offs between detail and convenience. For instance, a very detailed classification, with numerous complexly shaped regions derived from a large set of variables, may be most useful for the evaluation of climate models (Rubel and Kottek, 2010; Belda et al., 2015; Beck et al., 2018a) and climate projections (Feng et al., 2014; Belda et al., 2016). In contrast, geometrically simple regions are often best suited for regional climate modelling and downscaling (e.g., the Coordinated Regional Climate Downscaling Experiment (CORDEX) domains; see Giorgi and Gutowski, 2015, and Section 1.5.3).

1.4.5.2 Types of regions used in AR6

IPCC's recognition of the importance of regional climates can be traced back to its First Assessment Report (IPCC, 1990a), where climate projections for 2030 were presented for five subcontinental regions (see Section 1.3.6 for an assessment of those projections). In subsequent reports, there has been a growing emphasis on the analysis of regional climate, including two special reports: one on regional impacts (IPCC, 1998) and another on extreme events (SREX, IPCC, 2012). A general feature of previous IPCC reports is that the number and coverage of climate regions vary according to the subject and across WGs. Such varied definitions have the advantage of optimizing the results for a particular application (e.g., national boundaries are crucial for decision making, but they rarely delimit distinctive climate regions), whereas variable region definitions may have the disadvantage of hindering multidisciplinary assessments and comparisons between studies or WGs.

In this Report, regional climate change is primarily addressed through the introduction of four classes of regions (unless otherwise explicitly mentioned and justified). The first two are the unified WGI Reference Sets of (1) Land and (2) Ocean Regions, which are used in the entire Report. These are supplemented by additional sets of (3) Typological Regions — used in Chapters 5, 8–12 and Atlas — and (4) Continental Regions, which are mainly used for linking Chapters 11, 12 and Atlas with WGII (Figure 1.18). All four classes of regions are defined and described in detail in the Atlas. Here we summarize their basic features.

[START FIGURE 1.18 HERE]

Figure 1.18: Main types of regions used in this report. (a) AR6 WGI Reference Set of Land and Ocean Regions (Iturbide et al., 2020), consisting of 46 land regions and 15 ocean regions, including 3 hybrid regions (CAR, MED, SEA) that are both land and ocean regions. Acronyms are explained on the right of the map. Notice that RAR, SPO, NPO and EPO extend beyond the 180º meridian, therefore appearing at both sides of the map (indicated by dashed lines). A comparison with the previous reference regions of AR5 WGI (IPCC, 2013a) is presented in the Atlas. (b) Example of typological regions: monsoon domains adopted in Chapter 8. Acronyms are explained on the right of the map. The black contour lines represent the global monsoon zones, while the coloured regions denote the regional monsoon domains. The two stippled regions (EqAmer and SAfri) do receive seasonal rainfall, but their classification as monsoon regions is still under discussion. (c) Continental Regions used mainly in Chapter 12 and the Atlas. Stippled zones define areas that are assessed in both regions (e.g., the Caribbean is assessed as Small Islands and also as part of Central America). Small Islands are ocean regions containing small islands with consistent climate signals and/or climatological coherence.

[END FIGURE 1.18 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Reference Land and Ocean Regions are polygonal, sub-continental domains defined through a combination of environmental, climatic and non-climatic (e.g., pragmatic, technical, historical) factors, in accordance with the literature and climatological reasoning based on observed and projected future climate. Merging the diverse functions and purposes of the regions assessed in the literature into a common reference set implies a certain degree of compromise between simplicity, practicality, and climate consistency. For instance, Spain is fully included in the Mediterranean (MED) Reference Region, but is one of the most climatically diverse countries in the world. Likewise, a careful comparison of panels (a) and (b) of Figure 1.18) reveals that the simplified southern boundary of the Sahara (SAH) Reference Region slightly overlaps the northern boundary of the West African Monsoon Typological Region. As such, the resulting Reference Regions are not intended to precisely represent climates, but rather to provide simple domains suitable for regional synthesis of observed and modelled climate and climate change information (Iturbide et al., 2020). In particular, CMIP6 model results averaged over Reference Regions are presented in the Atlas.

The starting point for defining the AR6 Reference Sets of Land Regions was the collection of 26 regions introduced in SREX (IPCC, 2012). The SREX collection was then revised, reshaped, complemented and optimized to reflect the recent scientific literature and observed climate-change trends, giving rise to the novel AR6 reference set of 46 land regions. Additionally, AR6 introduces a new reference set of 15 ocean regions (including 3 hybrid regions that are treated as both, land and ocean), which complete the coverage of the whole Earth (Iturbide et al., 2020).

Particular aspects of regional climate change are described by specialized domains called Typological Regions (Figure 1.18b). These regions cover a wide range of spatial scales and are defined by specific features, called typologies. Examples of typologies include: tropical forests, deserts, mountains, monsoon regions, and megacities, among others. Typological Regions are powerful tools to summarize complex aspects of climate defined by a combination of multiple variables. For this reason, they are used in many chapters of AR6 WGI and WGII (e.g., Chapters 8–12 and the Atlas).

Finally, consistency with WGII is also pursued in Chapter 11, 12 and Atlas through the use of a set of Continental Regions (Figure 1.18c), based on the nine continental domains defined in AR5 WGII Part B (Hewitson et al., 2014). These are classical geopolitical divisions of Africa, Asia, Australasia, Europe, North America, Central and South America, plus Small Islands, Polar Regions, and the Ocean. In AR6 WGI, five hybrid zones (Caribbean–Small islands, East Europe–Asia, European Arctic, North American Arctic, and North Central America) are also identified, which are assessed in more than one continental region. Additional consistency with WGIII is pursued by Chapter 6 through the use of sub-continental domains which essentially form a subset of the Continental Set of Regions (Figure 1.18c and Chapter 6, Section 6.1).

1.5 Major developments and their implications

This section presents a selection of key developments since the AR5 of the capabilities underlying the lines of evidence used in the present report: observational data and observing systems (Section 1.5.1), new developments in reanalyses (Section 1.5.2), climate models (Section 1.5.3), and modelling techniques, comparisons and performance assessments (Section 1.5.4). For brevity, we focus on the developments that are of particular importance to the conclusions drawn in later chapters, though we also provide an assessment of potential losses of climate observational capacity.

1.5.1 Observational data and observing systems

Progress in climate science relies on the quality and quantity of observations from a range of platforms: surface-based instrumental measurements, aircraft, radiosondes and other upper-atmospheric observations, satellite-based retrievals, ocean observations, and paleoclimatic records. An historical perspective to these types of observations is presented in Section 1.3.1.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Observed large-scale climatic changes assessed in Chapter 2, attribution of these changes in Chapter 3, and regional observations of specific physical or biogeochemical processes presented in other Chapters, are supported by improvements in observational capacity since the AR5. Attribution assessments can be made at a higher likelihood level than AR5, due in part to the availability of longer observational datasets (Chapter 3). Updated assessments are made based on new and improved datasets, for example of global temperature change (Cross-Chapter Box 2.3 in Chapter 2) or regional climate information (Chapter 10, Section 10.2). Of particular relevance to the AR6 assessment are the 'Essential Climate Variables' (ECVs, Hollmann et al., 2013; Bojinski et al., 2014), and 'Essential Ocean Variables' (EOVs; Lindstrom et al., 2012), compiled by the Global Climate Observing System (GCOS; WMO, 2016), and the Global Ocean Observing System (GOOS), respectively. These variables include physical, chemical, and biological variables or groups of linked variables and underpin 'headline indicators' for climate monitoring (Trewin et al., 2021).

We highlight below the key advances in observational capacity since the AR5, including major expansions of existing observational platforms as well as new and/or emerging observational platforms that play a key role in AR6. We then discuss potential near-term losses in key observational networks due to climate change or other adverse human-caused influence.

1.5.1.1 Major expansions of observational capacity

Atmosphere, land and hydrological cycle

Satellites provide observations of a large number of key atmospheric and land surface variables, ensuring sustained observations over wide areas. Since AR5, such observations have expanded to include satellite retrievals of atmospheric CO_2 via the NASA Orbiting Carbon Observatory satellites (OCO-2 and OCO-3, Eldering et al., 2017), following on from similar efforts employing the Greenhouse Gases Observing Satellite (GOSAT, Yokota et al., 2009; Inoue et al., 2016). Improved knowledge of fluxes between the atmosphere and land surface results from combining remote sensing and in situ measurements (Rebmann et al., 2018). FLUXNET (https://fluxnet.org/) has been providing eddy covariance measurements of carbon, water, and energy fluxes between the land and the atmosphere, with some of the stations operating for over 20 years (Pastorello et al., 2017), while the Baseline Surface Radiation Network (BSRN) has been maintaining high-quality radiation observations since the 1990s (Ohmura et al., 1998; Driemel et al., 2018).

Observations of the composition of the atmosphere have been further improved through expansions of existing surface observation networks (Bodeker et al., 2016; De Mazière et al., 2018) and through in situ measurements such as aircraft campaigns (Chapter 2, Section 2.2; Chapter 5, Section 5.2; Chapter 6, Section 6.2). Examples of expanded networks include Aerosols, Clouds, and Trace Gases Research InfraStructure (ACTRIS) (Pandolfi et al., 2018), which focuses on short-lived climate forcers, and the Integrated Carbon Observation System (ICOS), which allows scientists to study and monitor the global carbon cycle and greenhouse gas emissions (Colomb et al., 2018). Examples of recent aircraft observations include the Atmospheric Tomography Mission (ATom), which has flown repeatedly along the north-south axis of both the Pacific and Atlantic oceans, and the continuation of the In-service Aircraft for a Global Observing System (IAGOS) effort, which measures atmospheric composition from commercial aircraft (Petzold et al., 2015).

Two distinctly different but important remote sensing systems can provide information about temperature and humidity since the early 2000s. Global Navigation Satellite Systems (e.g., GPS) radio occultation and limb soundings provide information, although only data for the upper troposphere and lower stratosphere are suitable to support climate change assessments (Angerer et al., 2017; Scherllin-Pirscher et al., 2017; Steiner et al., 2019; Gleisner et al., 2020). These measurements complement those from the Atmospheric Infrared Sounder (AIRS; Chahine et al., 2006). AIRS has limitations in cloudy conditions, although these limitations have been partly solved using new methods of analysis (Blackwell and Milstein, 2014; Susskind et al., 2014). These new data sources now have a sufficient length of the record to strengthen the analysis of atmospheric warming in Chapter 2, Section 2.3.1.2.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Assessments of the hydrological cycle in Chapters 2 and 8 are supported by longer time series and new developments. Examples are new satellites (McCabe et al., 2017) and measurements of water vapor using commercial laser absorption spectrometers and water vapor isotopic composition (Steen-Larsen et al., 2015; Zannoni et al., 2019). Data products of higher quality have been developed since AR5, such as the multi-source weighted ensemble precipitation (Beck et al., 2017), and multi-satellite terrestrial evaporation (Fisher et al., 2017). Longer series are available for satellite-derived global inundation (Prigent et al., 2020). Observations of soil moisture are now available via the Soil Moisture and Ocean Salinity (SMOS) and the Soil Moisture Active Passive (SMAP) satellite retrievals, filling critical gaps in the observation of hydrological trends and variability over land (Dorigo et al., 2017). Similarly, the Gravity Recovery and Climate Experiment GRACE and GRACE-FO satellites (Tapley et al., 2019) have provided key constraints on groundwater variability and trends around the world (Frappart and Ramillien, 2018). The combination of new observations with other sources of information has led to updated estimates of heat storage in inland waters (Vanderkelen et al., 2020), contributing to revised estimates of heat storage on the continents (von Schuckmann et al., 2020; Chapter 7, Section 7.2.2.3).

The ongoing collection of information about the atmosphere as it evolves is supplemented by the reconstruction and digitization of data about past conditions. Programs aimed at recovering information from sources such as handwritten weather journals and ship logs continue to make progress, and are steadily improving spatial coverage and extending our knowledge backward in time. For example, Brönnimann et al. (2019) has recently identified several thousand sources of climate data for land areas in the pre-1890 period, with many from the 18th century. The vast majority of these data are not yet contained in international digital data archives, and substantial quantities of undigitized ship's weather log data exist for the same period (Kaspar et al., 2015). Since the AR5 there has been a growth of 'citizen science' activities to rapidly transcribe substantial quantities of weather observations involving volunteers. Examples of projects include: oldWeather.org, and SouthernWeatherDiscovery.org that both used ship-based logbook sources, and the DRAW (Data Rescue: Archival and Weather) project, WeatherRescue.org, JungleWeather.org and the Climate History Australia project, which recovered land-based station data from Canada, Europe, the Congo and Australia respectively (e.g., Park et al., 2018; Hawkins et al., 2019). Undergraduate students have also been recruited to successfully digitise rainfall data in Ireland (Ryan et al., 2018). Such observations are an invaluable source of weather and climate information for the early historical period that continues to expand the digital archives (e.g., Freeman et al., 2017) which underpin observational datasets used across several Chapters.

Ocean

Observations of the ocean have expanded significantly since the AR5, with expanded global coverage of in situ ocean temperature and salinity observations, in situ ocean biogeochemistry observations, and satellite retrievals of a variety of EOVs. Many recent advances are extensively documented in a compilation by Lee et al. (2019). Below we discuss those most relevant for the current assessment.

Argo is a global network of nearly 4000 autonomous profiling floats (Roemmich et al., 2019), delivering detailed constraints on the horizontal and vertical structure of temperature and salinity across the global ocean. Argo has greatly expanded since AR5, including biogeochemistry and measurements deeper than 2000 m (Jayne et al., 2017), and the longer timeseries enable more rigorous climate assessments of direct relevance to estimates of ocean heat content (Chapter 2, Section 2.3.3.1 ; Chapter 7, section 7.2.2.2). Argo profiles are complemented by animal-borne sensors in several key areas, such as the seasonally ice-covered sectors of the Southern Ocean (Harcourt et al., 2019).

Most basin-scale arrays of moored ocean instruments have expanded since AR5, providing decades-long records of the ocean and atmosphere properties relevant for climate, such as the El Niño-Southern Oscillation (Chen et al., 2018), deep convection (de Jong et al., 2018) or transports through straits (Woodgate, 2018). Key basin-scale arrays include transport-measuring arrays in the Atlantic Ocean, continuing (McCarthy et al., 2020) or newly added since AR5 (Lozier et al., 2019), supporting the assessment of regional ocean circulation (Chapter 9, section 9.2.3). Tropical ocean moorings in the Pacific,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Indian and Atlantic oceans include new sites, improved capability for real time transmission, and new oxygen and CO_2 sensors (Bourlès et al., 2019; Hermes et al., 2019; Smith et al., 2019b).

A decade of observations of sea-surface salinity is now available via the SMOS and SMAP satellite retrievals, providing continuous and global monitoring of surface salinity in the open ocean and coastal areas for the first time (Vinogradova et al., 2019; Reul et al., 2020) (Chapter 9, Section 9.2.2.2).

The global network of tide gauges, complemented by a growing number of satellite-based altimetry datasets, allows for more robust estimates of global and regional sea level rise (Chapter 2, Section 2.3.3.3; Chapter 9, Section 9.6.1.3). Incorporating vertical land motion derived from the Global Positioning System (GPS), the comparison with tide gauges has allowed the correction of a drift in satellite altimetry series over the period 1993–1999 (Watson et al., 2015; Chen et al., 2017), thus improving our knowledge of the recent acceleration of sea level rise (Chapter 2, Section 2.3.3.3). These datasets, combined with Argo and observations of the cryosphere, allow a consistent closure of the global mean sea level budget (Cross-Chapter Box 9.1 in Chapter 9; WCRP Global Sea Level Budget, 2018).

Cryosphere

For the cryosphere, there has been much recent progress in synthesizing global datasets covering larger areas and longer time periods from multi-platform observations. For glaciers, the Global Terrestrial Network for Glaciers, which combines data on glacier fluctuations, mass balance and elevation change with glacier outlines and ice thickness, has expanded and provided input for assessing global glacier evolution and its role in sea level rise (Chapter 2, Section 2.3.2.3; Chapter 9, Section 9.5.1; Zemp et al., 2019). New data sources include archived and declassified aerial photographs and satellite missions, and high-resolution (10 m or less) digital elevation models (Porter et al., 2018; Braun et al., 2019).

Improvements have also been made in the monitoring of permafrost. The Global Terrestrial Network for Permafrost (Biskaborn et al., 2015) provides long-term records of permafrost temperature and active layer thickness at key sites to assess their changes over time. Substantial improvements to our assessments of large-scale snow changes come from intercomparison and blending of several datasets, for snow water equivalent (Mortimer et al., 2020) and snow cover extent (Mudryk et al., 2020), and from bias corrections of combined datasets using in situ data (Pulliainen et al., 2020; Chapter 2, Section 2.3.2.5; Chapter 9, Section 9.5.2).

The value of gravity-based estimates of changes in ice sheet mass has increased as the time series from the GRACE and GRACE-FO satellites, homogenised and absolutely calibrated, is close to 20 years in length. The ESA's Cryosat-2 radar altimetry satellite mission has continued to provide measurements of the changes in the thickness of sea ice and the elevation of the Greenland and Antarctic Ice Sheets (Tilling et al., 2018). Other missions include NASA's Operation IceBridge, collecting airborne remote sensing measurements to bridge the gap between ICESat (Ice, Cloud and land Elevation Satellite) and the upcoming ICESat-2 laser altimetry missions. Longer time series from multiple missions have led to considerable advances in understanding the origin of inconsistencies between the mass balances of different glaciers and reducing uncertainties in estimates of changes in the Greenland and Antarctic Ice Sheets (Bamber et al., 2018; Shepherd et al., 2018a, 2020). Last, the first observed climatology of snowfall over Antarctica was obtained using the cloud/precipitation radar onboard NASA's CloudSat (Palerme et al., 2014).

Biosphere

Satellite observations have recently expanded to include data on the fluorescence of land plants as a measure of photosynthetic activity via the Global Ozone Monitoring Experiment (Guanter et al., 2014; Yang et al., 2015) and OCO-2 satellites (Sun et al., 2017). Climate data records of Leaf Area Index (LAI), characterizing the area of green leaves per unit of ground area, and the fraction of absorbed photosynthetically active radiation (FAPAR) – an important indicator of photosynthetic activity and plant health (Gobron et al., 2009) – are now available for over 30-years (Claverie et al., 2016). In addition, key indicators such as fire disturbances/burned areas are now retrieved via satellite (Chuvieco et al., 2019). In the US, the National

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Ecological Observational Network (NEON) provides continental-scale observations relevant to the assessment of changes in aquatic and terrestrial ecosystems via a wide variety of ground-based, airborne, and satellite platforms (Keller et al., 2008). All these long-term records reveal range shifts in ecosystems (Chapter 2, Section 2.3.4).

The ability to estimate changes in global land biomass has improved due to the use of different microwave satellite data (Liu et al., 2015) and in situ forest census data and co-located lidar, combined with the MODerate resolution Imaging Spectroradiometer (MODIS; Baccini et al., 2017). This has allowed for improved quantification of land temperature (Duan et al., 2019), carbon stocks and human-induced changes due to deforestation (Chapter 2, Section 2.2.7). Time series of Normalized Difference Vegetation Index (NDVI) from MODIS and other remote sensing platforms is widely applied to assess the effects of climate change on vegetation in drought-sensitive regions (Atampugre et al., 2019). New satellite imaging capabilities for meteorological observations, such as the advanced multi-spectral imager aboard Himawari-8 (Bessho et al., 2016), also allow for improved monitoring of challenging quantities such as seasonal changes of vegetation in cloudy regions (Miura et al., 2019; Chapter 2, section 2.3.4.3).

In the ocean, efforts are underway to coordinate observations of biologically-relevant EOVs around the globe (Muller-Karger et al., 2018; Canonico et al., 2019) and to integrate observations across disciplines (e.g., the Global Ocean Acidification Observing Network; Tilbrook et al., 2019). A large number of coordinated field campaigns during the 2015/2016 El Niño event enabled the collection of short-lived biological phenomena such as coral bleaching and mortality caused by a months-long ocean heatwave (Hughes et al., 2018); beyond this event, coordinated observations of coral reef systems are increasing in number and quality (Obura et al., 2019). Overall, globally coordinated efforts focused on individual components of the biosphere (e.g., the Global Alliance of Continuous Plankton Recorder Surveys; Batten et al., 2019) contribute to improved knowledge of the changing marine ecosystems (Chapter 2, Section 2.3.4.2).

Given widespread evidence for decreases in global biodiversity in recent decades related to climate change and other forms of human disturbance (IPBES, 2019), a new international effort to identify a set of Essential Biodiversity Variables is underway (Pereira et al., 2013; Navarro et al., 2017).

In summary, the observational coverage of ongoing changes to the climate system is improved at the time of AR6, relative to what was available for AR5 (*high confidence*).

Paleoclimate

Major paleo reconstruction efforts completed since AR5 include a variety of large-scale, multi-proxy temperature datasets and associated reconstructions spanning the last 2000 years (PAGES 2k Consortium, 2017, 2019; Neukom et al., 2019), the Holocene (Kaufman et al., 2020), the Last Glacial Maximum (Cleator et al., 2020; Tierney et al., 2020b), the Mid-Pliocene Warm Period (McClymont et al., 2020), and the Early Eocene Climate Optimum (Hollis et al., 2019). Newly compiled borehole data (Cuesta-Valero et al., 2019), as well as advances in statistical applications to tree ring data, result in more robust reconstructions of key indices such as Northern Hemisphere temperature over the last millennium (e.g., Wilson et al., 2016; Anchukaitis et al., 2017). Such reconstructions provide a new context for recent warming trends (Chapter 2) and serve to constrain the response of the climate system to natural and anthropogenic forcing (Chapters 3 and 7).

Ongoing efforts have expanded the number of large-scale, tree-ring-based drought reconstructions that span the last centuries to millennium at annual resolution (Chapter 8; Cook et al., 2015; Stahle et al., 2016; Aguilera-Betti et al., 2017; Morales et al., 2020). Likewise, stalagmite records of oxygen isotopes have increased in number, resolution, and geographic distribution since AR5, providing insights into regional to global-scale hydrological change over the last centuries to millions of years (Chapter 8; Cheng et al., 2016; Denniston et al., 2016; Comas-Bru and Harrison, 2019). A new global compilation of water isotope-based paleoclimate records spanning the last 2,000 years (PAGES Iso2K) lays the groundwork for quantitative multi-proxy reconstructions of regional to global scale hydrological and temperature trends and extremes (Konecky et al., 2020).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Recent advances in the reconstruction of climate extremes beyond temperature and drought include expanded datasets of past El Niño-Southern Oscillation extremes (Chapter 2, Section 2.4.2; e.g., Barrett et al., 2018; Freund et al., 2019; Grothe et al., 2019) and other modes of variability (Hernández et al., 2020), hurricane activity (e.g., Burn and Palmer, 2015; Donnelly et al., 2015), jet stream variability (Trouet et al., 2018), and wildfires (e.g., Taylor et al., 2016).

New datasets as well as recent data compilations and syntheses of sea level over the last millennia (Kopp et al., 2016; Kemp et al., 2018), the last 20,000 years (Khan et al., 2019), the last interglacial period (Dutton et al., 2015; Chapter 2, Section 2.3.3.3), and the Pliocene (Dumitru et al., 2019; Grant et al., 2019; Cross-Chapter Box 2.4 in Chapter 2) help constrain sea level variability and its relationship to global and regional temperature variability, and to contributions from different sources on centennial to millennial timescales (Chapter 9, Section 9.6.2).

Reconstructions of paleoocean pH (Chapter 2, Section 2.3.3.5) have increased in number and accuracy, providing new constraints on ocean pH across the last centuries (e.g., Wu et al., 2018), the last glacial cycles (e.g., Moy et al., 2019), and the last several million years (e.g., Anagnostou et al., 2020). Such reconstructions inform processes and act as benchmarks for Earth system models of the global carbon cycle over the recent geologic past (Chapter 5, Section 5.3.1), including previous high-CO_2 warm intervals such as the Pliocene (Cross-Chapter Box 2.4 in Chapter 2). Particularly relevant to such investigations are reconstructions of atmospheric CO_2 (Hönisch et al., 2012; Foster et al., 2017) that span the past millions to tens of millions of years.

Constraints on the timing and rates of past climate changes have improved since AR5. Analytical methods have increased the precision and reduced sample-size requirements for key radiometric dating techniques including radiocarbon (Gottschalk et al., 2018; Lougheed et al., 2018) and Uranium-Thorium dating (Cheng et al., 2013). More accurate ages of many paleoclimate records are also facilitated by recent improvements in the radiocarbon calibration datasets (IntCal20, Reimer et al., 2020). A recent compilation of global cosmogenic nuclide-based exposure dates (Balco, 2020b) allows for a more rigorous assessment of the evolution of glacial landforms since the Last Glacial Maximum (Balco, 2020a).

Advances in paleoclimate data assimilation (Chapter 10, Section 10.2.3.2) leverage the expanded set of paleoclimate observations to create physically consistent gridded fields of climate variables for data-rich intervals of interest (e.g., over the last millennium, Hakim et al. 2016) or last glacial period (Cleator et al., 2020; Tierney et al., 2020b). Such efforts mirror advances in our understanding of the relationship between proxy records and climate variables of interest, as formalized in so-called proxy system models (e.g., Tolwinski-Ward et al., 2011; Dee et al., 2015; Dolman and Laepple, 2018).

Overall, the number, temporal resolution, and chronological accuracy of paleoclimate reconstructions have increased since AR5, leading to improved understanding of climate system processes (or Earth system processes) (*high confidence*).

1.5.1.2 Threats to observational capacity or continuity

The lock-downs and societal outcomes arising due to the COVID-19 pandemic pose a new threat to observing systems. For example, WMO and UNESCO-IOC published a summary of the changes to Earth system observations during COVID-19 (WMO, 2020b). Fewer aircraft flights (down 75–90% in May 2020, depending on region) and ship transits (down 20% in May 2020) mean that onboard observations from those networks have reduced in number and frequency (James et al., 2020; Ingleby et al., 2021). Europe has deployed more radiosonde soundings to account for the reduction in data from air traffic. Fewer ocean observing buoys were deployed during 2020, and reductions have been particularly prevalent in the tropics and Southern Hemisphere. The full consequences of the pandemic and responses will come to light over time. Estimates of the effect of the reduction in aircraft data assimilation on weather forecasting skill are small (James et al., 2020; Ingleby et al., 2021), potentially alleviating concerns about veracity of future

ACCEPTED VERSION SUBJECT TO FINAL EDITS

atmospheric reanalyses of the COVID-19 pandemic period.

Surface-based networks have reduced in their coverage or range of variables measured due to COVID-19 and other factors. Over land, several factors, including the ongoing transition from manual to automatic observations of weather, have reduced the spatial coverage of certain measurement types including rainfall intensity, radiosonde launches and pan evaporation, posing unique risks to datasets used for climate assessment (WMO, 2017; Lin and Huybers, 2019). Ship-based measurements, which are important for ocean climate and reanalyses through time (Smith et al., 2019c), have been in decline due to the number of ships contributing observations. There has also been a decline in the number of variables recorded by ships, but an increase in the quality and time-resolution of others (e.g., sea level pressure, Kent et al. 2019).

Certain satellite frequencies are used to detect meteorological features that are vital to climate change monitoring. These can be disturbed by certain radio communications (Anterrieu et al., 2016), although scientists work to remove noise from the signal (Oliva et al., 2016). For example, water vapour in the atmosphere naturally produces a weak signal at 23.8 gigahertz, which is within the range of frequencies of the 5G communications network (Liu et al., 2021). Concern has been raised about potential leakage from 5G network transmissions into the operating frequencies of passive sensors on existing weather satellites, which could adversely influence their ability to remotely observe water vapour in the atmosphere (Yousefvand et al., 2020).

Threats to observational capacity also include the loss of natural climate archives that are disappearing as a direct consequence of warming temperatures. Ice core records from vulnerable alpine glaciers in the tropics (Permana et al., 2019) and the mid-latitudes (Gabrielli et al., 2016; Winski et al., 2018; Moreno et al., 2021) document more frequent melt layers in recent decades, with glacial retreat occurring at a rate and geographic scale that is unusual in the Holocene (Solomina et al., 2015). The scope and severity of coral bleaching and mortality events have increased in recent decades (Hughes et al., 2018), with profound implications for the recovery of coral climate archives from new and existing sites. An observed increase in the mortality of larger, long-lived trees over the last century is attributed to a combination of warming, land use change, and disturbance (e.g., McDowell et al., 2020). The ongoing loss of these natural, high-resolution climate archives endanger an end in their coverage over recent decades, given that many of the longest monthly- to annually-resolved paleoclimate records were collected in the 1960s to 1990s (e.g., the PAGES2K database as represented in PAGES 2k Consortium, 2017). This gap presents a barrier to the calibration of existing decades-to-centuries-long records needed to constrain past temperature and hydrology trends and extremes.

Historical archives of weather and climate observations contained in ship's logs, weather diaries, observatory logbooks and other sources of documentary data are also at jeopardy of loss from natural disasters or accidental destruction. These include measurements of temperature (air and sea surface), rainfall, surface pressure, wind strength and direction, sunshine amount, and many other variables back into the 19th century. While internationally coordinated data rescue efforts are focused on recovering documentary sources of past weather and climate data (e.g., Allan et al., 2011), no such coordinated efforts exist for vulnerable paleoclimate archives. Furthermore, oral traditions about local and regional weather and climate from indigenous peoples represent valuable sources of information, especially when used in combination with instrumental climate data (Makondo and Thomas, 2018), but are in danger of being lost as indigenous knowledge-holders pass away.

In summary, while the quantity, quality, and diversity of climate system observations have grown since AR5, the loss or potential loss of several critical components of the observational network is also evident (*high confidence*).

1.5.2 New developments in reanalyses

Reanalyses are usually the output of a model (e.g., a numerical weather prediction model) constrained by observations using data assimilation techniques, but the term has also been used to describe observation-based datasets produced using simpler statistical methods and models (see Annex I). This section focuses on

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the model-based methods and their recent developments.

Reanalyses complement datasets of observations in describing changes through the historical record and are sometimes considered as 'maps without gaps' because they provide gridded output in space and time, often global, with physical consistency across variables on sub-daily timescales, and information about sparsely-observed variables (such as evaporation) (Hersbach et al., 2020). They can be globally complete, or regionally focussed and constrained by boundary conditions from a global reanalysis (Chapter 10, Section 10.2.1.2). They can also provide feedback about the quality of the observations assimilated, including estimates of biases and critical gaps for some observing systems.

Many early reanalyses are described in Box 2.3 of Hartmann et al. (2013). These were often limited by the underlying model, the data assimilation schemes and observational issues (Thorne and Vose, 2010; Zhou et al., 2018). Observational issues include the lack of underlying observations in some regions, changes in the observational systems over time (e.g., spatial coverage, introduction of satellite data), and time-dependent errors in the underlying observations or in the boundary conditions, which may lead to stepwise biases in time. The assimilation of sparse or inconsistent observations can introduce mass or energy imbalances (Valdivieso et al., 2017; Trenberth et al., 2019). Further limitations and some efforts to reduce the implications of these observational issues will be detailed below.

The methods used in the development of reanalyses have progressed since AR5 and, in some cases, this has important implications for the information they provide on how the climate is changing. Annex I includes a list of reanalysis datasets used in the AR6. Recent major developments in reanalyses include the assimilation of a wider range of observations, higher spatial and temporal resolution, extensions further back in time, and greater efforts to minimise the influence of a temporally varying observational network.

Atmospheric reanalyses

Extensive improvements have been made in global atmospheric reanalyses since AR5. The growing demand for high-resolution data has led to the development of higher-resolution atmospheric reanalyses, such as the Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA2; Gelaro et al., 2017) and ERA5 (Hersbach et al., 2020). There is a focus on ERA5 here because it has been assessed as of high enough quality to present temperature trends alongside more traditional observational datasets (Chapter 2, Section 2.3.1.1) and is also used in the Interactive Atlas.

Atmospheric reanalyses that were assessed in AR5 are still being used in the literature, and results from ERA-Interim (Dee et al., 2011, ~80 km resolution, production stopped in August 2019), the Japanese 55-year Reanalysis (JRA-55) (Ebita et al., 2011; Kobayashi et al., 2015; Harada et al., 2016) and Climate Forecast System Reanalysis (CFSR) (Saha et al., 2010) are assessed in AR6. Some studies still also use the NCEP/NCAR reanalysis, particularly because it extends back to 1948 and is updated in near real-time (Kistler et al., 2001). Older reanalyses have a number of limitations, which have to be accounted for when assessing the results of any study that uses them.

ERA5 provides hourly atmospheric fields at about 31 km resolution on 137 levels in the vertical, as well as land surface variables and ocean waves, and is available from 1979 onwards and is updated in near real-time, with plans to extend back to 1950. A 10-member ensemble is also available at coarser resolution, allowing uncertainty estimates to be provided (e.g., Chapter 2, Section 2.3). MERRA-2 includes many updates from the earlier version, including the assimilation of aerosol observations, several improvements to the representation of the stratosphere, including ozone, and improved representations of cryospheric processes. All of these improvements increase the usefulness of these reanalyses (Hoffmann et al., 2019; Chapter 7, Section 7.3).

Models of atmospheric composition and emission sources and sinks allow the forecast and reanalysis of constituents such as O_3, CO, NO_x and aerosols. The Copernicus Atmosphere Monitoring Service (CAMS) reanalysis shows improvement against earlier atmospheric composition reanalyses, giving greater confidence for its use to study trends and evaluate models (e.g., Inness et al., 2019; Chapter 7, Section 7.3).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

The inter-comparison of reanalyses with each other, or with earlier versions, is often done for particular variables or aspects of the simulation. ERA5 is assessed as the most reliable reanalysis for climate trend assessment (Chapter 2, Section 2.3). Compared to ERA-Interim, the ERA5 forecast model and assimilation system, as well as the availability of improved reprocessing of observations, resulted in relatively smaller errors when compared to observations, including a better representation of global energy budgets, radiative forcing from volcanic eruptions (e.g., Mt. Pinatubo: Allan et al., 2020), the partitioning of surface energy (Martens et al., 2020) and wind (Kaiser-Weiss et al., 2015, 2019; Borsche et al., 2016; Scherrer, 2020). In ERA5, higher resolution means a better representation of Lagrangian motion convective updrafts, gravity waves, tropical cyclones, and other meso- to synoptic-scale features of the atmosphere (Hoffmann et al., 2019; Martens et al., 2020). Low-frequency variability is found to be generally well represented and, from 10 hPa downwards, patterns of anomalies in temperature match those from the ERA-Interim, MERRA-2 and JRA-55 reanalyses. Inhomogeneities in the water cycle have also been reduced (Hersbach et al., 2020).

Precipitation is not usually assimilated in reanalyses and, depending on the region, reanalysis precipitation can differ from observations by more than the observational error (Zhou and Wang, 2017; Sun et al., 2018; Alexander et al., 2020; Bador et al., 2020), although these studies did not include ERA5. Assimilation of radiance observations from microwave imagers which, over ice-free ocean surfaces, improve the analysis of lower-tropospheric humidity, cloud liquid water and ocean surface wind speed have resulted in improved precipitation outputs in ERA5 (Hersbach et al., 2020). Global averages of other fields, particularly temperature, from ERA-Interim and JRA-55 reanalyses continue to be consistent over the last 20 years with surface observational data sets that include the polar regions (Simmons and Poli, 2015), although biases in precipitation and radiation can influence temperatures regionally (Zhou et al., 2018). The global average surface temperature from MERRA-2 is far cooler in recent years than temperatures derived from ERA-Interim and JRA-55, which may be due to the assimilation of aerosols and their interactions (see Chapter 2, Section 2.3).

A number of regional atmospheric reanalyses (see Chapter 10, Section 10.2.1.2) have been developed, such as COSMO-REA (Wahl et al., 2017), and the Australian Bureau of Meteorology Atmospheric high-resolution Regional Reanalysis for Australia (BARRA) (Su et al., 2019). Regional reanalyses can add value to global reanalyses due to the lower computational requirements, and can allow multiple numerical weather prediction models to be tested (e.g., Kaiser-Weiss et al., 2019). There is some evidence that these higher resolution reanalyses better capture precipitation variability than global lower resolution reanalyses (Jermey and Renshaw, 2016; Cui et al., 2017) and are further assessed in Chapter 10, Section 10.2.1.2 and used in the Interactive Atlas.

In summary, the improvements in atmospheric reanalyses, and the greater number of years since the routine ingestion of satellite data began relative to AR5, mean that there is increased confidence in using atmospheric reanalyses products alongside more standard observation-based datasets in AR6 (*high confidence*).

Sparse input reanalyses of the instrumental era

Although reanalyses such as ERA5 take advantage of new observational datasets and present a great improvement in atmospheric reanalyses, the issues introduced by the evolving observational network remain. Sparse input reanalyses, where only a limited set of reliable and long observed records are assimilated, address these issues, with the limitation of fewer observational constraints. These efforts are sometimes called centennial-scale reanalyses. One example is the atmospheric 20th Century Reanalysis (Compo et al., 2011; Slivinski et al., 2021) which assimilates only surface and sea-level pressure observations, and is constrained by time-varying observed changes in atmospheric constituents, prescribed sea surface temperatures and sea ice concentration, creating a reconstruction of the weather over the whole globe every 3 hours for the period 1806–2015. The ERA-20C atmospheric reanalysis (covering 1900–2010; Poli et al., 2016) also assimilates marine wind observations, and CERA-20C is a centennial-scale reanalysis that assimilates both atmospheric and oceanic observations for the 1901–2010 period (Laloyaux et al., 2018). These centennial-scale reanalyses are often run as ensembles that provide an estimate of the uncertainty in the simulated variables over space and time. Slivinski et al. (2021) conclude that the uncertainties in surface

ACCEPTED VERSION SUBJECT TO FINAL EDITS

circulation fields in version 3 of the 20th Century Reanalysis are reliable and that there is also skill in its tropospheric reconstruction over the 20th century. Long-term changes in other variables, such as precipitation, also agree well with direct observation-based datasets (Chapter 2, Section 2.3.1.3; Chapter 8, Section 8.3.2.8).

Ocean reanalyses

Since AR5, ocean reanalyses have improved due to: increased model resolution (Zuo et al., 2017; Lellouche et al., 2018; Heimbach et al., 2019); improved physics (Storto et al., 2019); improvements in the atmospheric forcing from atmospheric reanalyses (see preceding subsection); and improvements in the data quantity and quality available for assimilation (e.g., Lellouche et al., 2018; Heimbach et al., 2019), particularly due to Argo observations (Zuo et al., 2019) (see Annex I).

The first Ocean Reanalyses Intercomparison project (Balmaseda et al., 2015) focussed on the uncertainty in key climate indicators, such as ocean heat content (Palmer et al., 2017), thermosteric sea level (Storto et al., 2017, 2019), salinity (Shi et al., 2017), sea ice extent (Chevallier et al., 2017), and the AMOC (Karspeck et al., 2017). Reanalysis uncertainties occur in areas of inhomogeneous or sparse observational data sampling, such as for the deep ocean, the Southern Ocean and western boundary currents (Lellouche et al., 2018; Storto et al., 2019). Intercomparisons have also been dedicated to specific variables such as mixed-layer depths (Toyoda et al., 2017), eddy kinetic energy (Masina et al., 2017) of the polar regions (Uotila et al., 2019). Karspeck et al. (2017) found disagreement in the Atlantic meridional overturning circulation (AMOC)` variability and strength in reanalyses over observation-sparse periods, whereas Jackson et al. (2019) reported a lower spread in AMOC strength across an ensemble of ocean reanalyses of the recent period (1993-2010) linked to improved observation availability for assimilation. Reanalyses also have a larger spread of ocean heat uptake than data-only products and can produce spurious overestimates of heat uptake (Palmer et al., 2017), which is important in the context of estimating climate sensitivity (Storto et al., 2019). The ensemble approach for ocean reanalyses provides another avenue for estimating uncertainties across ocean reanalyses (Storto et al., 2019).

While there are still limitations in their representation of oceanic features, ocean reanalyses add value to observation-only based products and are used to inform assessments in AR6 (Chapters 2, 3, 7 and 9). Reanalyses of the atmosphere or ocean alone may not account for important atmosphere-ocean coupling, motivating the development of coupled reanalyses (Laloyaux et al., 2018; Schepers et al., 2018; Penny et al., 2019), but these are not assessed in AR6.

Reanalyses of the pre-instrumental era

Longer reanalyses that extend further back in time than the beginning of the instrumental record are being developed. They include the complete integration of paleoclimate archives and newly available early instrumental data into extended reanalysis datasets. Such integration leverages ongoing development of climate models that can simulate paleoclimate records in their units of analysis (i.e., oxygen isotope composition, tree ring width, etc.), in many cases using physical climate variables as input for so-called 'proxy system models' (Evans et al., 2013; Dee et al., 2015). Ensemble Kalman filter data assimilation approaches allow to combine paleoclimate data and climate model data to generate annually resolved fields (Last Millenium Reanalysis, Hakim et al., 2016; Tardif et al., 2018) or even monthly fields (Franke et al., 2017). This allows for a greater understanding of decadal variability (Parsons and Hakim, 2019) and greater certainty around the full range of the frequency and severity of climate extremes, allowing for better-defined detection of change. It also helps to identify the links between biogeochemical cycles, ecosystem structure and ecosystem functioning, and to provide initial conditions for further model experiments or downscaling (see Chapter 2).

Applications of reanalyses

The developments in reanalyses described above mean that they are now used across a range of applications. In AR6, reanalyses provide information for fields and in regions where observations are limited. There is

ACCEPTED VERSION SUBJECT TO FINAL EDITS

growing confidence that modern reanalyses can provide another line of evidence in describing recent temperature trends (see Chapter 2, Tables 2.4 and 2.5) As their spatial resolution increases, the exploration of fine-scale extremes in both space and time becomes possible (e.g., wind; Kaiser-Weiss et al., 2015). Longer reanalyses can be used to describe the change in the climate over the last 100 to 1000 years. Reanalyses have been used to help post-process climate model output, and drive impact models, however, they are often bias adjusted first (e.g., Weedon et al., 2014). See Cross-Chapter Box 10.2 in Chapter 10. Copernicus Climate Change Service (C3S) provides a bias adjusted dataset for global land areas based on ERA5 called WFDE5 (Cucchi et al., 2020) which, combined with ERA5 information over the ocean (W5E5; Lange, 2019), is used as the AR6 Interactive Atlas reference for the bias adjustment of model output.

The growing interest in longer-term climate forecasts (from seasonal to multi-year and decadal) means that reanalyses are now more routinely being used to develop the initial state for these forecasts, such as for the Decadal Climate Prediction Project (DCPP; Boer et al., 2016). Ocean reanalyses are now being used routinely in the context of climate monitoring, (e.g., the Copernicus Marine Environment Monitoring Service Ocean State Report; von Schuckmann et al., 2019).

In summary, reanalyses have improved since AR5 and can increasingly be used as a line of evidence in assessments of the state and evolution of the climate system (*high confidence*). Reanalyses provide consistency across multiple physical quantities, and information about variables and locations that are not directly observed. Since AR5, new reanalyses have been developed with various combinations of increased resolution, extended records, more consistent data assimilation, estimation of uncertainty arising from the range of initial conditions, and an improved representation of the atmosphere or ocean system. While noting their remaining limitations, the WGI Report uses the most recent generation of reanalysis products alongside more standard observation-based datasets.

1.5.3 Climate Models

A wide range of numerical models are widely used in climate science to study the climate system and its behaviour across multiple temporal and spatial scales. These models are the main tools available to look ahead into possible climate futures under a range of scenarios (see Section 1.6). Global Earth System Models (ESMs) are the most complex models which contribute to AR6. At the core of each ESM is a GCM (General Circulation Model) representing the dynamics of the atmosphere and ocean. ESMs are complemented by regional models (see Chapter 10, Section 10.3.1) and by a hierarchy of models of lower complexity. This section summarizes major developments in these different types of models since AR5. Past IPCC reports have made use of multi-model ensembles generated through various phases of the World Climate Research Programme (WCRP) Coupled Model Intercomparison Project (CMIP). Analysis of the latest CMIP Phase 6 (CMIP6, Eyring et al., 2016) simulations constitute a key line of evidence supporting this assessment report (see Section 1.5.4). The key characteristics of models participating in CMIP6 are listed in Annex II.

1.5.3.1 Earth System Models

Earth system models are mathematical formulations of the natural laws that govern the evolution of climate-relevant systems: atmosphere, ocean, cryosphere, land, and biosphere, and the carbon cycle (Flato, 2011). They build on the fundamental laws of physics (e.g., Navier-Stokes or Clausius-Clapeyron equations) or empirical relationships established from observations and, when possible, constrained by fundamental conservation laws (e.g., mass and energy). The evolution of climate-relevant variables is computed numerically using high performance computers (André et al., 2014; Balaji et al., 2017), on three-dimensional discrete grids (Staniforth and Thuburn, 2012). The spatial (and temporal) resolution of these grids in both the horizontal and vertical directions determines which processes need to be parameterised or whether they can be explicitly resolved. Developments since AR5 in model resolution, parameterizations and modelling of the land and ocean biosphere and of biogeochemical cycles are discussed below.

Model grids and resolution

ACCEPTED VERSION SUBJECT TO FINAL EDITS

The horizontal resolution and the number of vertical levels in ESMs is generally higher in CMIP6 than in CMIP5 (Figure 1.19). Global models with finer horizontal grids represent better many aspects of the circulation of the atmosphere (Gao et al., 2020; Schiemann et al., 2020) and ocean (Bishop et al., 2016; Storkey et al., 2018), bringing improvements in the simulation of the global hydrological cycle (Roberts et al., 2018). CMIP6 includes a dedicated effort (HighResMIP, Haarsma et al., 2016) to explore the effect of higher horizontal resolution, such as ~50 km, ~25 km and even ~10 km (see 1.5.4.2 and Annex II, Table AII.6). Improvements are documented in the highest resolution coupled models used for HighResMip (Hewitt et al., 2017b; Roberts et al., 2019). Flexible grids allowing spatially variable resolution are more widely used than at the time of the AR5 in the atmosphere (McGregor, 2015; Giorgetta et al., 2018) and in the ocean (Wang et al., 2014; Petersen et al., 2019).

The number of vertical levels in the atmosphere of global models has increased (Figure 1.19) partly to enable simulations to include higher levels in the atmosphere and better represent stratospheric processes (Charlton-Perez et al., 2013; Kawatani et al., 2019). Half the modelling groups now use 'high top' models with a top level above the stratopause (a pressure of about 1 hPa). The number of vertical levels in the ocean models has also increased in order to achieve finer resolution over the water column and especially in the upper mixed layer, and better resolve the diurnal cycle (Bernie et al., 2008) (see Chapter 3, Section 3.5 and Annex II).

Despite the documented progress of higher resolution, the model evaluation carried out in subsequent chapters shows that improvements between CMIP5 and CMIP6 remain modest at the global scale (Bock et al., 2020; Chapter 3, Section 3.8.2). Lower resolution alone does not explain all model biases, for example, a low blocking frequency (Davini and D'Andrea, 2020) or a wrong shape of the Intertropical Convergence Zone (Tian and Dong, 2020). Model performance depends on model formulation and parameterizations as much as on resolution (Chapter 3, Chapter 8, Chapter 10).

[START FIGURE 1.19 HERE]

Figure 1.19: Resolution of the atmospheric and oceanic components of global climate models participating in CMIP5, CMIP6, and HighResMIP: (a) (b) horizontal resolution (km), and (c) (d) number of vertical levels. Darker colour circles indicate high-top models (whose top of the atmosphere is above 50 km). The crosses are the median values. These models are documented in Annex II. Note that duplicated models in a modelling group are counted as one entry when their horizontal and vertical resolutions are same. For HighResMIP, one atmosphere-ocean coupled model with the highest resolution from each modelling group is used. The horizontal resolution (rounded to 10km) is the square root of the number of grid points divided by the surface area of the Earth, or the number of surface ocean grid points divided by the area of the ocean surface, for the atmosphere and ocean respectively.

[END FIGURE 1.19 HERE]

Representation of physical and chemical processes in ESMs

Atmospheric models include representations of physical processes such as clouds, turbulence, convection and gravity waves that are not fully represented by grid-scale dynamics. The CMIP6 models have undergone updates in some of their parameterization schemes compared to their CMIP5 counterparts, with the aim of better representing the physics and bringing the climatology of the models closer to newly available observational datasets. Most notable developments are to schemes involving radiative transfer, cloud microphysics, and aerosols, in particular a more explicit representation of the aerosol indirect effects through aerosol-induced modification of cloud properties. Broadly, aerosol-cloud microphysics has been a key topic for the aerosol and chemistry modelling communities since AR5, leading to improved understanding of the climate influence of short-lived climate forcers, but they remain the single largest source of spread in ESM calculations of climate sensitivity (Meehl et al., 2020), with numerous parameterization schemes in use (Gettelman and Sherwood, 2016; Zhao et al., 2018; Gettelman et al., 2019). See also Chapter 6, section 6.4. The treatment of droplet size and mixed-phase clouds (liquid and ice) was found to lead to changes in

ACCEPTED VERSION SUBJECT TO FINAL EDITS

climate sensitivity (Annex VII: Glossary) of some models between AR5 and AR6 (Bodas-Salcedo et al., 2019; Gettelman et al., 2019; Zelinka et al., 2020, Chapter 7, Section 7.4).

The representation of ocean and cryosphere processes has also evolved significantly since CMIP5. The explicit representation of ocean eddies, due to increased grid resolution (typically, from 1° to ¼°), is a major advance in a number of CMIP6 ocean model components (Hewitt et al., 2017b). Advances in sea ice models have been made, for example, through correcting known shortcomings in CMIP5 simulations, in particular the persistent underestimation of the rapid decline in summer Arctic sea ice extent (Rosenblum and Eisenman, 2016, 2017; Turner and Comiso, 2017; Notz and Stroeve, 2018). The development of glacier and ice-sheet models has been motivated and guided by an improved understanding of key physical processes, including grounding line dynamics, stratigraphy and microstructure evolution, sub-shelf melting, and glacier and ice-shelf calving, among others (Faria et al., 2014, 2018; Hanna et al., 2020). The resolution of ice sheet models has continuously increased, including the use of nested grids, sub-grid interpolation schemes, and adaptive mesh approaches (Cornford et al., 2016), mainly for a more accurate representation of grounding-line migration and data assimilation (Pattyn, 2018). Ice-sheet models are increasingly interactively coupled with global and regional climate models, accounting for the height mass-balance feedback (Vizcaino et al., 2015; Le clec'h et al., 2019), and enabling a better representation of ice-ocean processes, in particular for the Antarctic Ice Sheet (Asay-Davis et al., 2017).

Sea level rise is caused by multiple processes acting on multiple time scales: ocean warming, glaciers and ice sheet melting, change in water storage on land, glacial isostatic adjustment (Chapter 9, Box 9.1) but no single model can represent all these processes (Chapter 9, Section 9.6). In this report, the contributions are computed separately (Chapter 9, Figure 9.28) and merged into a common probabilistic framework and updated from AR5 (Church et al., 2013; Kopp et al., 2014; Chapter 9, Section 9.6).

Another notable development since AR5 is the inclusion of stochastic parameterizations of sub-grid processes in some comprehensive climate models (Sanchez et al., 2016). Here, the deterministic differential equations that govern the dynamical evolution of the model are complemented by knowledge of the stochastic variability in unresolved processes. While not yet widely implemented, the approach has been shown to improve the forecasting skill of weather models, to reduce systematic biases in global models (Berner et al., 2017; Palmer, 2019) and to influence simulated climate sensitivity (Strommen et al., 2019).

Representation of biogeochemistry, including the carbon cycle

Since AR5, more sophisticated land use and land cover change representations in ESMs have been developed to simulate the effects of land management on surface fluxes of carbon, water and energy (Lawrence et al., 2016), although the integration of many processes (e.g., wetland drainage, fire as a management tool) remains a challenge (Pongratz et al., 2018). The importance of nitrogen availability to limit the terrestrial carbon sequestration has been recognised (Zaehle et al., 2014; Chapter 5, Section 5.4) and so an increasing number of models now include a prognostic representation of the terrestrial nitrogen cycle and its coupling to the land carbon cycle (Jones et al., 2016a; Arora et al., 2020), leading to a reduction in uncertainty for carbon budgets (Jones and Friedlingstein, 2020; Chapter 5, Section 5.1). As was the case in CMIP5 (Ciais et al., 2013), the land surface processes represented vary across CMIP6 models, with at least some key processes (fire, permafrost carbon, microbes, nutrients, vegetation dynamics, plant demography) absent from any particular ESM land model (Chapter 5, Table 5.4). Ocean biogeochemical models have evolved to enhance the consistency of the exchanges between ocean, atmosphere and land, through riverine input and dust deposition (Stock et al., 2014; Aumont et al., 2015). Other developments include flexible plankton stoichiometric ratios (Galbraith and Martiny, 2015), improvements in the representation of nitrogen fixation (Paulsen et al., 2017), and the limitation of plankton growth by iron (Aumont et al., 2015). Due to the long time scale of biogeochemical processes, spin-up strategies have been shown to affect the performance of models used in AR5 (Séférian et al., 2016).

1.5.3.2 Model tuning and adjustment

When developing climate models, choices have to be made in a number of areas. Besides model formulation

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and resolution, parameterizations of unresolved processes also involve many choices as, for each of these, several parameters can be set. The acceptable range for these parameters is set by mathematical consistency (e.g., convergence of a numerical scheme), physical considerations (e.g., energy conservation), observations, or a combination of factors. Model developers choose a set of parameters that both falls within this range and mimics observations of individual processes or their statistics.

An initial set of such choices is usually made by (often extensive) groups of modellers working on individual components of the Earth system (e.g., ocean, atmosphere, land or sea ice). As components are assembled to build an ESM, the choices are refined so that the simulated climate best represents a number of pre-defined climate variables, or 'tuning targets'. When these are met the model is released for use in intercomparisons such as CMIP. Tuning targets can be one of three types: mean climate, regional phenomena and features, and historical trends (Hourdin et al., 2017). One example of such a goal is that the climate system should reach a mean equilibrium temperature close to observations when energy received from the sun is close to its observed value. Whether tuning should be performed to accurate simulating long-term trends such as changes in global mean temperature over the historical era, or rather be performed for each process independently such that all collective behaviour is emergent, is an open question (Schmidt et al., 2017; Burrows et al., 2018).

Each modelling group has its own strategy and, after AR5, a survey was conducted to understand the tuning approach used in 23 CMIP5 modelling centres. The results are discussed in Hourdin et al. (2017), which stresses that the behaviour of ESMs depends on the tuning strategy. An important recommendation is that the calibration steps that lead to particular model tuning should be carefully documented. In CMIP6 each modelling group now describes the three levels of tuning, both for the complete ESM and for the individual components (available at https://explore.es-doc.org/ and in the published model descriptions, Annex II). The most important global tuning target for CMIP6 models is the net top-of-the-atmosphere (TOA) heat flux and its radiative components. Other global targets include: the decomposition of each of these TOA fluxes into a clear sky component and a component due to the radiative effect of clouds, global mean air and ocean temperature, sea ice extent, sea ice volume, glacial mass balance, global root mean square error of precipitation. The TOA heat flux balance is achieved using a diversity of approaches, usually unique to each modelling group. Adjustments are made for parameters associated with uncertain or poorly constrained processes (Schmidt et al., 2017), for example the aerosol indirect effects, adjustments to ocean albedo, marine dimethyl sulfide (DMS) parameterization, or cloud properties (Mauritsen and Roeckner, 2020).

Regional tuning targets include the meridional overturning circulation in the Atlantic Ocean, the Southern Ocean circulation and temperature profiles in ocean basins (Golaz et al., 2019; Sellar et al., 2019); regional land properties and precipitations (Mauritsen et al., 2019; Yukimoto et al., 2019), latitudinal distribution of radiation (Boucher et al., 2020), spatial contrasts in TOA radiative fluxes or surface fluxes, and stationary waves in the Northern Hemisphere (Schmidt et al., 2017; Yukimoto et al., 2019).

Even with some core commonalities of approaches to model tuning, practices can differ, such as the use of initial drift from initialized forecasts, the explicit use of the transient observed record for the historical period, or the use of the present-day radiative imbalance at the TOA as a tuning target rather than an equilibrated pre-industrial balance. The majority of CMIP6 modelling groups report that they do not tune their model for the observed trends during the historical period (23 out of 29), nor for equilibrium climate sensitivity (25 out of 29). ECS and TCR are thus emergent properties for a large majority of models. The effect of tuning on model skill and ensemble spread in CMIP6 is further discussed in Chapter 3, Section 3.3.

1.5.3.3 From global to regional models

The need for accurate climate information at the regional scale is increasing (Chapter 10, Section 10.1). High-resolution global climate models, such as those taking part in HighResMIP, provide more detailed information at the regional scale (Roberts et al., 2018). However, due to the large computational resources required by these models, only a limited number of simulations per model are available. In addition to CMIP global models, regional information can be derived using Regional Climate Models (RCMs) and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

downscaling techniques, presented in Chapter 10 and the Atlas. RCMs are dynamical models similar to GCMs that simulate a limited region and are forced with boudary conditions from a global simulation, often correcting for biases (Chapter 10, Section 10.3 and Cross-Chapter Box 10.2, Annex II). This approach allows the use of a higher resolution within the chosen domain, and thus better represent important drivers of regional climate such as mountain ranges, land management and urban effects. RCMs resolving atmospheric convection explicitly are now included in intercomparisons (Coppola et al., 2020) and used in Chapters 10, 11 and 12. Other approaches are also used to generate regional climate projections, such as statistical downscaling (Maraun and Widmann, 2018; Chapter 10, Section 10.3).

The number of climate centres or consortia that carry out global climate simulations and projections has grown from 11 in the first CMIP to 19 in CMIP5 and 28 for CMIP6 (see Section 1.5.4.2 and Annex II). Regional climate models participating in the Coordinated Regional Downscaling Experiment (CORDEX) are more diverse than the global ESMs (see Section 1.5.4.3 and Annex II) and engage an even wider international community (Figure 1.20).

[START FIGURE 1.20 HERE]

Figure 1.20: A world map showing the increased diversity of modelling centres contributing to CMIP and CORDEX. Climate models are often developed by international consortia. EC-Earth is shown as an example (involving SMHI, Sweden; KNMI, The Netherlands; DMI, Denmark; AEMET, Spain; Met Éireann, Ireland; CNR-ISAC, Italy; Instituto de Meteorologia, Portugal; FMI, Finland), but there are too many such collaborations to display all of them on this map. More complete information about institutions contributing to CORDEX and CMIP6 is found in Annex II.

[END FIGURE 1.20 HERE]

1.5.3.4 Models of lower complexity

Earth System Models of Intermediate Complexity (EMICs) complement the model hierarchy and fill the gap between conceptual, simple climate models and complex GCMs or ESMs (Claussen et al., 2002). EMICs are simplified; they include processes in a more parameterized, rather than explicitly calculated, form and generally have lower spatial resolution compared to the complex ESMs. As a result, EMICs require much less computational resource and can be integrated for many thousands of years without supercomputers (Hajima et al., 2014). The range of EMICs used in climate change research is highly heterogeneous, ranging from zonally averaged or mixed-layer ocean models coupled to statistical-dynamical models of the atmosphere to low-resolution 3-dimensional ocean models coupled to simplified dynamical models of the atmosphere. An increasing number of EMICs include interactive representations of the global carbon cycle, with varying levels of complexity and numbers of processes considered (Plattner et al., 2008; Zickfeld et al., 2013; MacDougall et al., 2020). Given the heterogeneity of the EMIC community, modelers tend to focus on specific research questions and develop individual models accordingly. As for any type of models assessed in this report, the set of EMICs undergoes thorough evaluation and fit-for-purpose testing before being applied to address specific climate aspects.

EMICs have been used extensively in past IPCC reports, providing long-term integrations on paleoclimate and future timescales, including stabilization pathways and a range of commitment scenarios, with perturbed physics ensembles and sensitivity studies, or with simulations targeting the uncertainty in global climate-carbon cycle systems (e.g., Meehl et al., 2007; Collins et al., 2013). More recently, a number of studies have pointed to the possibility of systematically different climate responses to external forcings in EMICs and complex ESMs (Frölicher and Paynter, 2015; Pfister and Stocker, 2017, 2018) that need to be considered in the context of this report. For example, Frölicher and Paynter (2015) showed that EMICs have a higher simulated realized warming fraction (i.e., the TCR/ECS ratio) than CMIP5 ESMs and speculated that this may bias the temperature response to zero carbon emissions. But, in a recent comprehensive multi-model analysis of the zero CO_2 emissions commitment, MacDougall et al. (2020) did not find any significant

ACCEPTED VERSION SUBJECT TO FINAL EDITS

differences in committed temperatures 90 years after halting emissions between EMICs and ESMs. While some EMICs contribute to parts of the CMIP6-endorsed MIPs, a coordinated EMICs modeling effort similar to the ones for the AR4 (Plattner et al., 2008) and AR5 (Eby et al., 2013; Zickfeld et al., 2013) is not in place for IPCC AR6; however, EMICs are assessed in a number of chapters. For example, Chapters 4 and 5 use EMICs in the assessment of long-term climate change beyond 2100 (Chapter 5, Section 5.5), zero-emission commitments, overshoot and recovery (Chapter 4, Section 4.7), consequences of carbon dioxide removal (CDR) on the climate system and the carbon cycle (Chapter 4, Sections 4.6 and Chapter 5, Section 5.6) and long-term carbon cycle–climate feedbacks (Chapter 5, Section 5.4).

Physical emulators and simple climate models make up a broad class of heavily parametrized models designed to reproduce the responses of the more complex, process-based models, and provide rapid translations of emissions, via concentrations and radiative forcing, into probabilistic estimates of changes to the physical climate system. The main application of emulators is to extrapolate insights from ESMs and observational constraints to a larger set of emission scenarios (see Cross-Chapter Box 7.1 in Chapter 7). The computational efficiency of various emulating approaches opens new analytical possibilities given that ESMs take a lot of computational resources for each simulation. The applicability and usefulness of emulating approaches are however constrained by their skill in capturing the global mean climate responses simulated by the ESMs (mainly limited to global-mean or hemispheric land/ocean temperatures) and by their ability to extrapolate skilfully outside the calibrated range.

The terms emulator and simple climate model (SCM) are different, although they are sometimes used interchangeably. SCM refers to a broad class of lower-dimensional models of the energy balance, radiative transfer, carbon cycle, or a combination of such physical components. SCMs can also be tuned to reproduce the calculations of climate-mean variables of a given ESM, assuming that their structural flexibility can capture both the parametric and structural uncertainties across process-oriented ESM responses. When run in this setup, they are termed emulators. Simple climate models do not have to be run in 'emulation' mode, though, as they can also be used to test consistency across multiple lines of evidence with regard to ranges in ECS, TCR, TCRE and carbon cycle feedbacks (see Chapters 5 and 7). Physical emulation can also be performed with very simple parameterisations ('one-or-few-line climate models'), statistical methods like neural networks, genetic algorithms, or other artificial intelligence approaches, where the emulator behaviour is explicitly tuned to reproduce the response of a given ESM or model ensemble (Chapters 4, 5, and 7).

Current emulators and SCMs include the generic impulse response model outlined in Chapter 8 of the AR5 (AR5-IR (Supplementary Material 8.SM.11 of Myhre et al. (2013)), two-layer models (Held et al., 2010; Rohrschneider et al., 2019; Nicholls et al., 2020), and higher complexity approaches that include upwelling, diffusion and entrainment in the ocean component (e.g., MAGICC Version 5.3 (Raper et al., 2001; Wigley et al., 2009), Version 6/7 (Meinshausen et al., 2011a)**;** OSCAR (Gasser et al., 2017); CICERO SCM (Skeie et al., 2017); FaIR (Millar et al., 2017b; Smith et al., 2018); and a range of statistical approaches (Schwarber et al., 2019; Beusch et al., 2020b)). An example of recent use of an emulator approach is an early estimate of the climate implications of the COVID-19 lockdowns (Forster et al. 2020; see Cross-Chapter Box 6.1 in Chapter 6).

Since AR5, simplified climate models have been developed further, and their use is increasing. Different purposes motivating development include: being as simple as possible for teaching purposes (e.g., a two-layer energy balance model), as comprehensive as possible to allow for propagation of uncertainties across multiple Earth System domains (MAGICC and others), or focus on higher complexity representation of specific domains (e.g., OSCAR). The common theme in many models is to improve parameterisations that reflect the latest findings in complex ESM interactions, such as the nitrogen cycle addition to the carbon cycle, or tropospheric and stratospheric ozone exchange, with the aim of emulating their global mean temperature response. Also, within the simple models that have a rudimentary representation of spatial heterogeneity (e.g., four-box simple climate models), the ambition is to represent heterogeneous forcers such as black carbon more adequately (Stjern et al., 2017), provide an appropriate representation of the forcing-feedback framework (see e.g., Sherwood et al., 2015), investigate new parameterisations of ocean heat uptake, and implement better representations of volcanic aerosol induced cooling (Gregory et al., 2016a).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

MAGICC (Wigley et al., 2009; Meinshausen et al., 2011a) and FaIR (Smith et al., 2018) were used in the SR1.5 (IPCC, 2018) to categorize mitigation pathways into classes of scenarios that peak near 1.5°C, overshoot 1.5°C, or stay below 2°C. The SR1.5 (Rogelj et al., 2018) concluded that there was a *high agreement* in the relative temperature response of pathways, but *medium agreement* on the precise absolute magnitude of warming, introducing a level of imprecision in the attribution of a single pathway to a given category.

In this Report, there are two notable uses of simple climate models. One is the connection between the assessed range of ECS in Chapter 7, and the projections of future global surface air temperature (GSAT) change in Chapter 4, which is done via a two-layer model based on Held et al. (2010). It is also used as input to sea level projections in Chapter 9. The other usage is the transfer of Earth system assessment knowledge to Working Group III, via a set of models (MAGICC, FaIR, CICERO-SCM) specifically tuned to represent the Working Group I assessment. For an overview of the uses, and an assessment of the related Reduced Complexity Model Intercomparison Project (RCMIP), see Nicholls et al. (2020) and Cross-Chapter Box 7.1 in Chapter 7.

[START BOX 1.3 HERE]

Box 1.3: Emission metrics in AR6 WGI

Emission metrics compare the radiative forcing, temperature change, or other climate effects arising from emissions of CO_2 versus those from emissions of non-CO_2 radiative forcing agents (such as CH_4 or N_2O). They have been discussed in the IPCC since the First Assessment Report and are used as a means of aggregating emissions and removals of different gases and placing them on a common ('CO_2 equivalent', or 'CO_2-eq') scale.

AR5 included a thorough assessment of common pulse emission metrics, and how these address various indicators of future climate change (Myhre et al., 2013). Most prominently used are the Global Warming Potentials (GWPs), which integrate the calculated radiative forcing contribution following an idealized pulse (or one-time) emission, over a chosen time horizon (IPCC, 1990a), or the Global Temperature-change Potential (GTP), which considers the contribution of emission to the global-mean temperature at a specific time after emission. Yet another metric is the Global Precipitation change Potential (GPP), used to quantify the precipitation change per unit mass of emission of a given forcing agent (Shine et al., 2015).

As an example of usage, the Paris Rulebook [Decision 18/CMA.1, annex, paragraph 37] states that 'Each Party shall use the 100-year time-horizon global warming potential (GWP) values from the IPCC Fifth Assessment Report, or 100-year time-horizon GWP values from a subsequent IPCC assessment report as agreed upon by the 'Conference of the Parties serving as the meeting of the Parties to the Paris Agreement' (CMA), to report aggregate emissions and removals of GHGs, expressed in CO_2-eq. Each Party may in addition also use other metrics (e.g., global temperature potential) to report supplemental information on aggregate emissions and removals of GHGs, expressed in CO_2-eq'.

Since AR5, improved knowledge of the radiative properties, lifetimes, and other characteristics of emitted species, and the response of the climate system, have led to updates to the numerical values of a range of metrics; see Chapter 7, Table 7.15. Another key development is a set of metrics that compare a pulse emission of CO_2 (as considered by GWP and GTP) to step-changes of emission rates for short-lived components (i.e., also considering emission trends). Termed GWP* (which also includes a pulse component) and Combined Global Temperature change Potential (CGTP), these metrics allow the construction of a near-linear relationship between global surface temperature change and cumulative CO_2 and CO_2-equivalent emissions of both short and long lived forcing agents (Allen et al., 2016; Cain et al., 2019; Collins et al., 2019). For example, the temperature response to a sustained methane reduction has a similar behaviour to the temperature response to a pulse CO_2 removal (or avoided emission).

In this Report, recent scientific developments underlying emission metrics, as relevant for Working Group I,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

are assessed in full in Chapter 7, Section 7.6. In particular, see Box 7.3, which discusses the choice of metric for different usages, and Section 7.6.1, which treats the challenge of comparing the climate implication of emissions of short-lived and long-lived compounds. Also, the choice of metric is of key importance when defining and quantifying net zeronet-zero greenhouse gas emissions; see Box 1.4 and Chapter 7, Section 7.6.2. Chapter 6 applies metrics to attribute GSAT change to short-lived climate forcer (SLCF) and long-lived greenhouse gas (LLGHG) emissions from different sectors and regions (Section 6.6.2).

The metrics assessed in this Report are also used, and separately assessed, by Working Group III. See Cross-Chapter Box 2: GHG emissions metrics and Annex B in Chapter 2 of the WGIII contribution to the AR6.

1.5.4 Modelling techniques, comparisons and performance assessments

Numerical models, however complex, cannot be a perfect representation of the real world. Results from climate modelling simulations constitute a key line of evidence for the present report, which requires considering the limitations of each model simulation. This section presents recent developments in techniques and approaches to robustly extract, quantify and compare results from multiple, independent climate models, and how their performance can be assessed and validated.

1.5.4.1 Model 'fitness for purpose'

A key issue addressed in this report is whether climate models are adequate or 'fit' for purposes of interest, that is, whether they can be used to successfully answer particular research questions, especially about the causes of recent climate change and the future evolution of climate (e.g., Parker, 2009; Notz, 2015; Knutti, 2018; Winsberg, 2018). Assessment of a model's fitness-for-purpose can be informed both by how the model represents relevant physical processes and by relevant performance metrics (Baumberger et al., 2017; Parker, 2020). The processes and metrics that are most relevant can vary with the question of interest, for example, a question about changes in deep ocean circulation versus a question about changes in regional precipitation (Notz, 2015; Gramelsberger et al., 2020). New model evaluation tools (Section 1.5.4.5) and emergent constraint methodologies (Section 1.5.4.7) can also aid the assessment of fitness-for-purpose, especially in conjunction with process understanding (Klein and Hall, 2015; Knutti, 2018). The broader availability of large model ensemble may allow for novel tests of fitness that better account for natural climate variability (see Section 1.5.4.2). Fitness-for-purpose of models used in this report is discussed in Chapter 3 (Section 3.8.4) for the global scale, in Chapter 10 (Section 10.3) for regional climate, and in the other chapters at the process level.

Typical strategies for enhancing the fitness-for-purpose of a model include increasing resolution in order to explicitly simulate key processes, improving relevant parameterizations, and careful tuning. Changes to a model that enhance its fitness for one purpose can sometimes decrease its fitness for others, by upsetting a pre-existing balance of approximations. When it is unclear whether a model is fit for a purpose of interest, there is often a closely-related purpose for which the evidence of fitness is clearer; for example, it might be unclear whether a model is fit for providing highly accurate projections of precipitation changes in a region, but reasonable to think that the model is fit for providing projections of precipitation changes that cannot yet be ruled out (Parker, 2009). Such information about plausible or credible changes can be useful to inform adaptation. Note that challenges associated with assessing model fitness-for-purpose need not prevent reaching conclusions with high confidence if there are multiple other lines of evidence supporting those same conclusions.

1.5.4.2 Ensemble modelling techniques

A key approach in climate science is the comparison of results from multiple model simulations with each

ACCEPTED VERSION SUBJECT TO FINAL EDITS

other and against observations. These simulations have typically been performed by separate models with consistent boundary conditions and prescribed emissions or radiative forcings, as in the Coupled Model Intercomparison Project phases (CMIP, Meehl et al., 2000, 2007a; Taylor et al., 2012; Eyring et al., 2016). Such multi-model ensembles (MMEs) have proven highly useful in sampling and quantifying model uncertainty, within and between generations of climate models. They also reduce the influence on projections of the particular sets of parametrizations and physical components simulated by individual models. The primary usage of MMEs is to provide a well quantified model range, but when used carefully they can also increase confidence in projections (Knutti et al., 2010). Presently, however, many models also share provenance (Masson and Knutti, 2011) and may have common biases that should be acknowledged when presenting and building on MME-derived conclusions (Boé, 2018; Abramowitz et al., 2019) (see Section 1.5.4.6).

Since AR5, an increase in computing power has made it possible to investigate simulated internal variability and to provide robust estimates of forced model responses, using Large Initial Condition Ensembles (ICEs), also referred to as Single Model Initial condition Large Ensembles (SMILEs). Examples using GCMs or ESMs that support assessments in AR6 include the CESM Large Ensemble (Kay et al., 2015), the MPI Grand Ensemble (Maher et al., 2019), and the CanESM2 large ensembles (Kirchmeier-Young et al., 2017). Such ensembles employ a single GCM or ESM in a fixed configuration, but starting from a variety of different initial states. In some experiments, these initial states only differ slightly. As the climate system is chaotic, such tiny changes in initial conditions lead to different evolutions for the individual realizations of the system as a whole. Other experiments start from a set of well-separated ocean initial conditions to sample the uncertainty in the circulation state of the ocean and its role in longer-timescale variations. These two types of ICEs have been referred to as 'micro' and 'macro' perturbation ensembles respectively (Hawkins et al., 2016). In support of this report, most models contributing to CMIP6 have produced ensembles of multiple realizations of their historical and scenario simulations (see Chapters 3 and 4).

Recently, the ICE technique has been extended to atmosphere-only simulations (Mizuta et al., 2017), single-forcer influences such as volcanic eruptions (Bethke et al., 2017) to regional modelling (Mote et al., 2015; Fyfe et al., 2017; Schaller et al., 2018; Leduc et al., 2019) and to attribution of extreme weather events using crowd-sourced computing (climateprediction.net; Massey et al., 2015).

ICEs can also be used to evaluate climate model parameterizations, if models are initialized appropriately (Phillips et al., 2004; Williams et al., 2013), mostly within the framework of seamless weather and climate predictions (e.g., Palmer et al., 2008; Hurrell et al., 2009; Brown et al., 2012). Initializing an atmospheric model in hindcast mode and observing the biases as they develop permits testing of the parameterized processes, by starting from a known state rather than one dominated by quasi-random short term variability (Williams et al., 2013; Ma et al., 2014; Vannière et al., 2014). However, single-model initial-conditions ensembles cannot cover the same degrees of freedom as a multi-model ensemble, because model characteristics substantially affect model behaviour (Flato et al., 2013).

A third common modelling technique is the perturbed parameter ensemble (PPE; note that the abbreviation also sometimes refers to the sub-category 'perturbed physics ensemble'). These methods are used to assess uncertainty based on a single model, with individual parameters perturbed to reflect the full range of their uncertainty (Murphy et al., 2004; Knutti et al., 2010; Lee et al., 2011; Shiogama et al., 2014). Statistical methods can then be used to detect which parameters are the main causes of uncertainty across the ensemble. PPEs have been used frequently in simpler models, such as EMICs, and are being applied to more complex models. A caveat of PPEs is that the estimated uncertainty will depend on the specific parameterizations of the underlying model and may well be an underestimation of the 'true' uncertainty. It is also challenging to disentangle forced responses from internal variability using a PPE alone.

Together, the three ensemble methods (MMEs, ICEs, PPEs) allow investigation of climate model uncertainty arising from internal variability, initial and internal boundary conditions, model formulations and parameterizations (Parker, 2013). Figure 1.21 illustrates the different ensemble types. Recent studies have also started combining multiple ensemble types or using ensembles in combination with statistical analytical techniques. For example, Murphy et al. (2018) combine MMEs and PPEs to give a fuller assessment of

ACCEPTED VERSION SUBJECT TO FINAL EDITS

modelling uncertainty. Wagman and Jackson (2018) use PPEs to evaluate the robustness of MME-based emergent constraints. Sexton et al. (2019) study the robustness of ICE approaches by identifying parameters and processes responsible for model errors at the two different timescales.

Overall, we assess that increases in computing power and the broader availability of larger and more varied ensembles of model simulations have contributed to better estimations of uncertainty in projections of future change (*high confidence*). Note, however, that despite their widespread use in climate science today, the cost of the ensemble approach in human and computational resources, and the challenges associated with the interpretation of multi-model ensembles, has been questioned (Palmer and Stevens, 2019; Touzé-Peiffer et al., 2020).

[START FIGURE 1.21 HERE]

Figure 1.21: Illustration of common types of model ensemble, simulating the time evolution of a quantity Q (such as global mean surface temperature). (a) Multi-model ensemble, where each model has its own realization of the processes affecting Q, and its own internal variability around the baseline value (dashed line). The multi-model mean (black) is commonly taken as the ensemble average. (b) Initial condition ensemble, where several realizations from a single model are compared. These differ only by minute ('micro') perturbations to the initial conditions of the simulation, such that over time, internal variability will progress differently in each ensemble member. (c) Perturbed physics ensemble, which also compares realizations from a single model, but where one or more internal parameters that may affect the simulations of Q are systematically changed to allow for a quantification of the effects of those quantities on the model results. Additionally, each parameter set may be taken as the starting point for an initial condition ensemble. In this figure, each set has three ensemble members.

1.5.4.3 The sixth phase of the Coupled Model Intercomparison Project (CMIP6)

The Coupled Model Intercomparison Project (CMIP) provides a framework to compare the results of different GCMs or ESMs performing similar experiments. Since its creation in the mid-1990s, it has evolved in different phases, involving all major climate modelling centres in the world (Figure 1.20). The results of these phases have played a key role in previous IPCC reports, and the present Report assesses a range of results from CMIP5 that were not published until after the AR5, as well as the first results of the 6th phase of CMIP (CMIP6) (Eyring et al., 2016). The CMIP6 experiment design is somewhat different from previous phases. It now consists of a limited set of DECK (Diagnostic, Evaluation and Characterization of Klima) simulations and an historical simulation that must be performed by all participating models, as well as a wide range of CMIP6-endorsed Model Intercomparison Projects (MIPs) covering specialized topics (Eyring et al., 2016) (see Figure 1.22). Each MIP activity consists of a series of model experiments, documented in the literature (see Table 1.3) and in an online database (https://es-doc.org, see Pascoe et al. (2019) and Annex II).

The CMIP DECK simulations form the basis for a range of assessments and projections in the following chapters. As in CMIP5, they consist of a 'pre-industrial' control simulation (piControl, where 'pre-industrial' is taken as fixed 1850 conditions in these experiments), an idealized, abrupt quadrupling of CO_2 concentrations relative to piControl (to estimate equilibrium climate sensitivity), a 1% per year increase in CO_2 concentrations relative to piControl (to estimate the transient climate response), and a transient simulation with prescribed sea-surface temperatures for the period 1979–2014 (termed 'AMIP' for historical reasons). In addition, all participating models perform a historical simulation for the period 1850–2014. For the latter, common CMIP6 forcings are prescribed (Cross-Chapter Box 1.4, Table 2). Depending on the model setup, these include emissions and concentrations of short-lived species (Hoesly et al., 2018; Gidden et al., 2019), long-lived greenhouse gases (Meinshausen et al., 2017), biomass burning emissions (van Marle et al., 2017), global gridded land use forcing data (Ma et al., 2020a), solar forcing (Matthes et al., 2017), and stratospheric aerosol data from volcanoes (Zanchettin et al., 2016). The methods for generating gridded datasets are described in (Feng et al., 2019). For AMIP simulations, common sea surface temperatures

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(SSTs) and sea ice concentrations (SICs) are prescribed. For simulations with prescribed aerosol abundances (i.e., not calculated from emissions), optical properties and fractional changes in cloud droplet effective radius are generally prescribed in order to provide a more consistent representation of aerosol forcing relative to earlier CMIP phases (Fiedler et al., 2017; Stevens et al., 2017). For models without ozone chemistry, time-varying gridded ozone concentrations and nitrogen deposition are also provided (Checa-Garcia et al., 2018).

Beyond the DECK and the historical simulations, the CMIP6-endorsed MIPs aim to investigate how models respond to specific forcings, their potential systematic biases, their variability, and their responses to detailed future scenarios such as the Shared Socioeconomic Pathways (SSPs, Section 1.6). Table 1.3 lists the 23 CMIP6-endorsed MIPs and key references. Results from a range of these MIPs, and many others outside of the most recent CMIP6 cycle, will be assessed in the following chapters (also shown in Table 1.3). References to all the CMIP6 datasets used in the report are found in Annex II, Table AII.10.

[START FIGURE 1.22 HERE]

Figure 1.22: Structure of CMIP6, the 6th phase of the Coupled Model Intercomparison Project. The centre shows the common DECK (Diagnostic, Evaluation and Characterization of Klima) and historical experiments that all participating models must perform. The outer circles show the topics covered by the endorsed (blue) and other MIPs (red). See Table 1.3 for explanation of the MIP acronyms. (Expanded from Eyring et al., 2016).

1.5.4.4 Coordinated Regional Downscaling Experiment (CORDEX)

The Coordinated Regional Downscaling Experiment (CORDEX, Gutowski Jr. et al., 2016) is an intercomparison project for regional models and statistical downscaling techniques, coordinating simulations on common domains and under common experimental conditions in a similar way to the CMIP effort. Dynamical and statistical downscaling techniques can provide higher-resolution climate information than is available directly from global climate models (Chapter 10, Section 10.3). These techniques require evaluation and quantification of their performance before they can be considered appropriate as usable regional climate information or be used in support of climate services. CORDEX simulations have been provided by a range of regional downscaling models, for 14 regions together covering much of the globe

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(Atlas, Figure Atlas.7), and they are used extensively in the AR6 WGI Atlas (Atlas.1.4; see also Annex II).

In support of AR6, CORDEX has undertaken a new experiment (CORDEX-CORE) where regional climate models downscale a common set of global model simulations, performed at a coarser resolution, to a spatial resolution spanning from 12 to 25 km over most of the CORDEX domains (Atlas, Box Atlas.1). CORDEX-CORE represents an improved level of coordinated intercomparison of downscaling models (Remedio et al., 2019).

1.5.4.5 Model Evaluation Tools

For the first time in CMIP, a range of comprehensive evaluation tools are now available that can run alongside the commonly used distributed data platform Earth System Grid Federation (ESGF, see Annex II), to produce comprehensive results as soon as the model output is published to the CMIP archive.

For instance, the Earth System Model Evaluation Tool (ESMValTool; Eyring et al., 2020; Lauer et al., 2020; Righi et al., 2020) is used by a number of chapters. It is an open-source community software tool that includes a large variety of diagnostics and performance metrics relevant for coupled Earth System processes, such as for the mean, variability and trends, and it can also examine emergent constraints (see Section 1.5.4.7). ESMValTool also includes routines provided by the WMO Expert Team on Climate Change Detection and Indices for the evaluation of extreme events (Min et al., 2011; Sillmann et al., 2013) and diagnostics for key processes and variability. Another example of evaluation tool is the CLIVAR 2020 ENSO metrics package (Planton et al., 2021).

These tools are used in several chapters of this report for the creation of the figures that show CMIP results. Together with the Interactive Atlas, they allow for traceability of key results, and an additional level of quality control on whether published figures can be reproduced. It also provides the capability to update published figures with, as much as possible, the same set of models in all figures, and to assess model improvements across different phases of CMIP (Chapter 3, Section 3.8.2).

These new developments are facilitated by the definition of common formats for CMIP model output (Balaji et al., 2018) and the availability of reanalyses and observations in the same format as CMIP output (obs4MIPs, Ferraro et al., 2015). The tools are also used to support routine evaluation at individual model centres and simplify the assessment of improvements of individual models or generations of model ensembles (Eyring et al., 2019). Note, however, that while tools such as ESMValTool can produce an estimate of overall model performance, dedicated model evaluation still needs to be performed when analysing projections for a particular purpose, such as assessing changing hazards in a given particular region. Such evaluation is discussed in the next section, and in greater detail in later chapters of this Report.

1.5.4.6 Evaluation of process-based models against observations

Techniques used for evaluating process-based climate models against observations were assessed in AR5 (Flato et al., 2013), and have progressed rapidly since (Eyring et al., 2019). The most widely used technique is to compare climatologies (long-term averages of specific climate variables) or time series of simulated (process-based) model output with observations, considering the observational uncertainty. A further approach is to compare the results of process-based models with those from statistical models. In addition to a comparison of climatological means, trends and variability, AR5 already made use of a large set of performance metrics for a quantitative evaluation of the models.

Since AR5, a range of studies has investigated model agreement with observations well beyond large scale mean climate properties (e.g., Bellenger et al., 2014; Covey et al., 2016; Pendergrass and Deser, 2017; Goelzer et al., 2018; Beusch et al., 2020a), providing information on the performance of recent model simulations across multiple variables and components of the Earth system (e.g., Anav et al., 2013; Guan and Waliser, 2017). Based on such studies, this Report assesses model improvements across different CMIP

ACCEPTED VERSION SUBJECT TO FINAL EDITS

DECK, CMIP6 historical and CMIP6-Endorsed MIP simulations, and of differences in model performance between different classes of models, such as high- versus low-resolution models (see e.g., Chapter 3, Section 3.8.2).

In addition, process- or regime-oriented evaluation of models has been expanded since AR5. By focusing on processes, causes of systematic errors in the models can be identified and insights can be gained as to whether a mean state or trend is correctly simulated for the right reasons. This approach is commonly used for the evaluation of clouds (e.g., Williams and Webb, 2009; Konsta et al., 2012; Bony et al., 2015; Dal Gesso et al., 2015; Jin et al., 2017), dust emissions (e.g., Parajuli et al., 2016; Wu et al., 2016) as well as aerosol-cloud (e.g., Gryspeerdt and Stier, 2012) and chemistry-climate (SPARC, 2010) interactions. Process-oriented diagnostics have also been used to evaluate specific phenomena such as the El Niño Southern Oscillation (ENSO, Guilyardi et al., 2016), the Madden–Julian Oscillation (MJO; Ahn et al., 2017; Jiang et al., 2018), Southern Ocean clouds (Hyder et al., 2018), monsoons (Boo et al., 2011; James et al., 2015), and tropical cyclones (Kim et al., 2018).

Instrument simulators provide estimates of what a satellite would see if looking down on the model simulated planet, and improve the direct comparison of modelled variables such as clouds, precipitation and upper tropospheric humidity with observations from satellites (e.g., Kay et al., 2011; Klein et al., 2013; Cesana and Waliser, 2016; Konsta et al., 2016; Jin et al., 2017; Chepfer et al., 2018; Swales et al., 2018; Zhang et al., 2018). Within the framework of the Cloud Feedback Model Intercomparison Project (CFMIP) contribution to CMIP6 (Webb et al., 2017), a new version of the Cloud Feedback Model Intercomparison Project Observational Simulator (COSP, Swales et al., 2018) has been released which makes use of a collection of observation proxies or satellite simulators. Related approaches in this rapidly evolving field include simulators for Arctic Ocean observations (Burgard et al., 2020) and measurements of aerosol observations along aircraft trajectories (Watson-Parris et al., 2019).

In this Report, model evaluation is performed in the individual chapters, rather than in a separate chapter as was the case for AR5. This applies to the model types discussed above, and also to dedicated models of subsystems that are not (or not yet) part of usual climate models, for example, glacier or ice sheet models (Annex II). Further discussions are found in Chapter 3 (attribution), Chapter 5 (carbon cycle), Chapter 6 (short-lived climate forcers), Chapter 8 (water cycle), Chapter 9 (ocean, cryosphere and sea level), Chapter 10 (regional scale information) and the Atlas (regional models).

1.5.4.7 Emergent constraints on climate feedbacks, sensitivities and projections

An emergent constraint is the relationship between an uncertain aspect of future climate change and an observable feature of the Earth System, evident across an ensemble of models (Allen and Ingram, 2002; Mystakidis et al., 2016; Wenzel et al., 2016; Hall et al., 2019; Winkler et al., 2019). Complex Earth System Models (ESMs) simulate variations on timescales from hours to centuries, telling us how aspects of the current climate relate to its sensitivity to anthropogenic forcing. Where an ensemble of different ESMs displays a relationship between a short-term observable variation and a longer-term sensitivity, an observation of the short-term variation in the real world can be converted, via the model-based relationship, into an 'emergent constraint' on the sensitivity. This is shown schematically in Figure 1.23 (Eyring et al., 2019), see also Annex VII: Glossary.

Emergent constraints use the spread in model projections to estimate the sensitivities of the climate system to anthropogenic forcing, providing another type of ensemble-wide information that is not readily available from simulations with one ESM alone. As emergent constraints depend on identifying those observable aspects of the climate system that are most related to climate projections, they also help to focus model evaluation on the most relevant observations (Hall et al., 2019). However, there is a chance that indiscriminate data-mining of the multi-dimensional outputs from ESMs could lead to spurious correlations (Caldwell et al., 2014; Wagman and Jackson, 2018) and less than robust emergent constraints on future changes (Bracegirdle and Stephenson, 2013). To avoid this, emergent constraints need to be tested 'out of sample' on parts of the dataset that were not included in its construction (Caldwell et al., 2018) and should

ACCEPTED VERSION SUBJECT TO FINAL EDITS

also always be based on sound physical understanding and mathematical theory (Hall et al., 2019). Their conclusions should also be reassessed when a new generation of MMEs becomes available, such as CMIP6. As an example, Chapter 7 (Section 7.5.4) discusses and assesses recent studies where equilibrium climate sensitivities (ECS) diagnosed in a multi-model ensemble are compared with the same models' estimates of an observable quantity, such as post-1970s global warming or tropical sea-surface temperatures of past climates like the last glacial maximum or the Pliocene. Assessments of other emergent constraints appear throughout later chapters, such as Chapter 4 (Section 4.2.5), Chapter 5 (Section 5.4.6) and Chapter 7 (Section 7.5.4).

[START FIGURE 1.23 HERE]

Figure 1.23: The principle of emergent constraints. An ensemble of models (blue dots) defines a relationship between an observable, mean, trend or variation in the climate (x-axis) and an uncertain projection, climate sensitivity or feedback (y-axis). An observation of the x-axis variable can then be combined with the model-derived relationship to provide a tighter estimate of the climate projection, sensitivity or feedback on the y-axis (adapted from Eyring et al. 2019).

[END FIGURE 1.23 HERE]

1.5.4.8 Weighting techniques for model comparisons

Assessments of climate model ensembles have commonly assumed that each individual model is of equal value ('model democracy') and when combining simulations to estimate the mean and variance of quantities of interest, they are typically unweighted (Haughton et al., 2015). This practice has been noted to diminish the influence of models exhibiting a good match with observations (Tapiador et al., 2020). However, exceptions to this approach exist, notably AR5 projections of sea ice, which only selected a few models which passed a model performance assessment (Collins et al., 2013), and more studies on this topic have appeared since the AR5 (e.g., Eyring et al., 2019). Ensembles are typically sub-selected by removing either poorly performing model simulations (McSweeney et al., 2015) or model simulations that are perceived to add little additional information, typically where multiple simulations have come from the same model. They may also be weighted based on model performance.

Several recent studies have attempted to quantify the effect of various strategies for selection or weighting of ensemble members based on some set of criteria (Haughton et al., 2015; Olonscheck and Notz, 2017; Sanderson et al., 2017). Model weighting strategies have been further employed since AR5 to reduce the spread in climate projections for a given scenario by using weights based on one or more model performance metrics (Wenzel et al., 2016; Knutti et al., 2017; Sanderson et al., 2017; Lorenz et al., 2018; Liang et al., 2020). However, models may share representations of processes, parameterization schemes, or even parts of code, leading to common biases. The models may therefore not be fully independent, calling into question inferences derived from multi-model ensembles (Abramowitz et al., 2019). Emergent constraints (see Section 1.5.4.5) also represent an implicit weighting technique that explicitly links present performance to future projections (Bracegirdle and Stephenson, 2013).

Concern has been raised about the large extent to which code is shared within the CMIP5 multi-model ensemble (Sanderson et al., 2015a). Boé (2018) showed that a clear relationship exists between the number of components shared by climate models and how similar the simulations are. The resulting similarities in behaviour need to be accounted for in the generation of best-estimate multi-model climate projections. This has led to calls to move beyond equally-weighted multi-model means towards weighted means that take into account both model performance and model independence (Sanderson et al., 2015b, 2017; Knutti et al., 2017). Model independence has been defined in terms of performance differences within an ensemble (Masson and Knutti, 2011; Knutti et al., 2013, 2017, Sanderson et al., 2015b, 2015a, 2017; Lorenz et al., 2018). However, this definition is sensitive to the choice of variable, observational data set, metric, time period, and region, and a performance ranked ensemble has been shown to sometimes perform worse than a

ACCEPTED VERSION SUBJECT TO FINAL EDITS

random selection (Herger et al., 2018a). The adequacy of the constraint provided by the data and experimental methods can be tested using a calibration-validation style partitioning of observations into two sets (Bishop and Abramowitz, 2013), or a 'perfect model approach' where one of the ensemble members is treated as the reference dataset and all model weights are calibrated against it (Bishop and Abramowitz, 2013; Wenzel et al., 2016; Knutti et al., 2017; Sanderson et al., 2017; Herger et al., 2018a, 2018b). Sunyer et al. (2014) use a Bayesian framework to account for model dependencies and changes in model biases. Annan and Hargreaves (2017) provides a statistical, quantifiable definition of independence that is independent of performance-based measures.

The AR5 quantified uncertainty in CMIP5 climate projections by selecting one realization per model per scenario, and calculating the 5–95% range of the resulting ensemble (see Chapter 4, Box 4.1) and the same strategy is generally still used in AR6. Broadly, the following chapters take the CMIP6 5–95% ensemble range as the *likely* uncertainty range for projections[8], with no further weighting or consideration of model ancestry and as long as no universal, robust method for weighting a multi-model projection ensemble is available (Box 4.1, Chapter 4). A notable exception to this approach is the assessment of future changes in global surface air temperature (GSAT), which also draws on the updated best estimate and range of equilibrium climate sensitivity assessed in Chapter 7. For a thorough description of the model weighting choices made in this Report, and the assessment of GSAT, see Chapter 4 (Box 4.1). Model selection and weighting in downscaling approaches for regional assessment is discussed in Chapter 10 (Section 10.3.4).

1.6 Dimensions of Integration: Scenarios, global warming levels and cumulative carbon emissions

This section introduces three ways to synthesize climate change knowledge across topics and chapters. These 'dimensions of integration' include (1) emission and concentration scenarios underlying the climate change projections assessed in this report, (2) levels of global mean surface warming relative to the 1850-1900 baseline ('global warming levels'), and (3) cumulative carbon emissions (Figure 1.24). All three dimensions can, in principle, be used to synthesize physical science knowledge across WGI, and also across climate change impacts, adaptation, and mitigation research. Scenarios, in particular, have a long history of serving as a common reference point within and across IPCC Working Groups and research communities. Similarly, cumulative carbon emissions and global warming levels provide key links between WGI assessments and those of the other WGs; these two dimensions frame the cause-effect chain investigated by WGI. The closest links to WGIII are the emissions scenarios, as WGIII considers drivers of emissions and climate change mitigation options. The links to WGII are the geophysical climate projections from the Earth System Models which the climate impacts and adaptation literature often uses as their starting point.

[START FIGURE 1.24 HERE]

Figure 1.24: The Dimensions of Integration across Chapters and Working Groups in the IPCC AR6 assessment. This report adopts three explicit dimensions of integration to integrate knowledge across chapters and Working Groups. The first dimension is scenarios, the second dimension is global-mean warming levels relative to 1850-1900, and the third dimension is cumulative CO_2 emissions. For the scenarios, illustrative 2100 end-points are also indicated (white circles). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.24 HERE]

The section is structured as follows: first, the scenarios used in AR6 are introduced and discussed in relation to scenarios used in earlier IPCC assessments (Section 1.6.1). Cross-Chapter Box 1.4 provides an overview of the new scenarios and how they are used in this report. Next, the two additional dimensions of integration are introduced: global warming levels (Section 1.6.2) and cumulative emissions (Section 1.6.3). Net zero

[8] Note that the 5–95% is a *very likely* range (See Box 1.1 on the use of calibrated uncertainty language in AR6), though if this is purely a multi-model likelihood range, it is generally treated as *likely*, in absence of other lines of evidence

ACCEPTED VERSION SUBJECT TO FINAL EDITS

emissions are discussed in Box 1.4. The relation between global warming levels and scenarios is further assessed in Cross-Chapter Box 11.1 in Chapter 11.

1.6.1 Scenarios

A scenario is a description of how the future may develop based on a coherent and internally consistent set of assumptions about key drivers including demography, economic processes, technological innovation, governance, lifestyles and relationships among these driving forces (IPCC, 2000; Rounsevell and Metzger, 2010; O'Neill et al., 2014; see Section 1.6.1.1). Scenarios can also be defined by geophysical driving forces only, such as emissions or abundances of greenhouse gases, aerosols, and aerosol precursors or land use patterns. Scenarios are not predictions; instead, they provide a 'what-if' investigation of the implications of various developments and actions (Moss et al., 2010). WGI investigates potential future climate change principally by assessing climate model simulations using emission scenarios originating from the WGIII community (Section 1.6.1.2). The scenarios used in this WGI report cover various hypothetical 'baseline scenarios' or 'reference futures' that could unfold in the absence of any or any additional climate policies (see Annex VII: Glossary). These 'reference scenarios' originate from a comprehensive analysis of a wide array of socio-economic drivers, such as population growth, technological development, and economic development, and their broad spectrum of associated energy, land use and emission implications (Riahi et al., 2017). With direct policy relevance to the Paris Agreement's 1.5°C and 'well below' 2°C goals, this report also assesses climate futures where the effects of additional climate change mitigation action are explored, i.e., so-called mitigation scenarios (for a broader discussion on scenarios and futures analysis, see Cross-Chapter Box 1, Table 1 in SRCCL, IPCC, 2019b).

For this Report, the main emissions, concentration and land use scenarios considered are a subset of scenarios recently developed using the Shared Socioeconomic Pathways framework (SSPs) (Riahi et al., 2017; see Section 1.6.1.1 and Cross-Chapter Box 1.4). Initially, the term 'SSP' described five broad narratives of future socio-economic development only (O'Neill et al., 2014). However, at least in the WGI community, the term 'SSP scenario' is now more widely used to refer directly to future emission and concentration scenarios that result from combining these socio-economic development pathways with climate change mitigation assumptions. These are assessed in detail in WGIII (WGIII, Chapter 3; Cross-Chapter Box 1.4, Table 1).

The WGI report uses a core set of five SSP scenarios to assist cross-Chapter integration and cross-WG applications: SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 (Cross-Chapter Box 1.4, Table 1). These scenarios span a wide range of plausible societal and climatic futures from potentially below 1.5°C best-estimate warming to over 4°C warming by 2100 (Figure 1.25). The set of five SSP scenarios includes those in 'Tier 1' simulations of the CMIP6 ScenarioMIP intercomparison project (O'Neill et al., 2016; see Section 1.5.4) that participating climate modelling groups were asked to prioritize (SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5), plus the low emission scenario SSP1-1.9. SSP1-1.9 is used in combination with SSP1-2.6 to explore differential outcomes of approximately 1.5 and 2.0 °C warming relative to pre-industrial levels, relevant to the Paris Agreement goals. Further SSP scenarios are used in this report to assess specific aspects, e.g., air pollution policies in Chapter 6 (Cross-Chapter Box 1.4). In addition, the previous generation of Representative Concentration Pathways (RCPs) is also used in this report when assessing future climate change (Section 1.6.1.3; Cross-Chapter Box 1.4, Table 1).

Climatic changes over the 21st century (and beyond) are projected and assessed in subsequent chapters, using a broad range of climate models, conditional on the various SSP scenarios. The projected future changes can then be put into the context of longer-term paleoclimate data and historical observations, showing how the higher emission and higher concentration scenarios diverge further from the range of climate conditions that ecosystems and human societies experienced in the past 2000 years in terms of global mean temperature and other key climate variables (Figure 1.26; see also Figure 1.5).

[START FIGURE 1.25 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Figure 1.25: Global mean surface air temperature (GSAT) illustrated as warming stripes from blue (cold) to red (warm) over three different time periods. From 1750 to 1850 based on PAGES 2K reconstructions (2017, 2019); from 1850 to 2018 showing the composite GSAT time series assessed in Chapter 2; and from 2020 onwards using the assessed GSAT projections for each Shared Socio-economic Pathway (SSP) (from Chapter 4). For the projections, the upper end of each arrow aligns with colour corresponding to the 95th percentile of the projected temperatures and the lower end aligns with the colour corresponding to the 5th percentile of the projected temperature range. Projected temperatures are shown for five scenarios from 'very low' SSP1-1.9 to 'very high' SSP5-8.5 (see Cross-Chapter Box 1.4 for more details on the scenarios). For illustrative purposes, natural variability has been added from a single CMIP6 Earth system model (MRI ESM2). The points in time when total CO_2 emissions peak, reach halved levels of the peak and reach net-zero emissions are indicated with arrows, '½' and '0' marks, respectively. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.25 HERE]

While scenarios are a key tool for integration across IPCC Working Groups, they also allow the integration of knowledge among scientific communities and across timescales. For example, agricultural yield, infrastructure and human health impacts of increased drought frequency, extreme rainfall events and hurricanes are often examined in isolation. New insights on climate impacts in WGII can be gained if compound effects of multiple cross-sectoral impacts are considered across multiple research communities under consistent scenario frameworks (Leonard et al., 2014; Warszawski et al., 2014; see also Chapter 11, Section 11.8). Similarly, a synthesis of WGI knowledge on sea level rise contributions is enabled by a consistent application of future scenarios across all specialised research communities, such as ice-sheet mass balance analyses, glacier loss projections and thermosteric change from ocean heat uptake (e.g. Kopp et al., 2014; see Chapter 9).

[START FIGURE 1.26 HERE]

Figure 1.26: Historical and projected future concentrations of CO_2, CH_4 and N_2O and global mean surface temperatures (GMST). GMST temperature reconstructions over the last 2000 years were compiled by the PAGES 2k Consortium (2017, 2019) (grey line, with 95% uncertainty range), joined by historical GMST timeseries assessed in Chapter 2 (black line) – both referenced against the 1850-1900 period. Future GSAT temperature projections are from CMIP6 ESM models across all concentration-driven SSP scenario projections (Chapter 4). The discontinuity around year 2100 for CMIP6 temperature projections results from the fact that not all ESM models ran each scenario past 2100. The grey vertical band indicates the future 2015-2300 period. The concentrations used to drive CMIP6 Earth System Models are derived from ice core, firn and instrumental datasets (Meinshausen et al., 2017) and projected using an emulator (Cross-Chapter Box 7.1 in Chapter 7; Meinshausen et al., 2020). The colours of the lines indicate the SSP scenarios used in this report (see Cross-Chapter Box 1.4, Figure 1). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.26 HERE]

In addition to the comprehensive SSP scenario set and the RCPs, multiple idealized scenarios and time-slice experiments using climate models are assessed in this report. Idealized scenarios refer to experiments where, for example, CO_2 concentrations are increased by 1% per year, or instantly quadrupled. Such idealized experiments have been extensively used in previous model intercomparison projects and constitute the core 'DECK' set of model experiments of CMIP6 (see Section 1.5.4). They are, for example, used to diagnose the patterns of climate feedbacks across the suite of models assessed in this report (Chapter 7).

In the following, we further introduce the SSP scenarios and how they relate to the Shared Socioeconomic Pathways framework (Section 1.6.1.1), describe the scenario generation process (Section 1.6.1.2), and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

provide a historical review of scenarios used in IPCC assessment reports (Section 1.6.1.3), before briefly discussing questions of scenario likelihood, scenario uncertainty and the use of scenario storylines (Section 1.6.1.4).

1.6.1.1 Shared Socio-economic Pathways

The Shared Socioeconomic Pathways SSP1 to SSP5 describe a range of plausible trends in the evolution of society over the 21st century. They were developed in order to connect a wide range of research communities (Nakicenovic et al., 2014) and consist of two main elements: a set of qualitative, narrative storylines describing societal futures (O'Neill et al., 2017a) and a set of quantified measures of development at aggregated and/or spatially resolved scales. Each pathway is an internally consistent, plausible and integrated description of a socio-economic future, but these socio-economic futures do not account for the effects of climate change, and no new climate policies are assumed. The SSPs' quantitative projections of socio-economic drivers include population, gross domestic product (GDP) and urbanization (Dellink et al., 2017; Jiang and O'Neill, 2017; Samir and Lutz, 2017). By design, the SSPs differ in terms of the socio-economic challenges they present for climate change mitigation and adaptation (Rothman et al., 2014; Schweizer and O'Neill, 2014) and the evolution of these drivers within each SSP reflects this design. Broadly, the five SSPs represent 'sustainability' (SSP1), a 'middle of the road' path (SSP2), 'regional rivalry' (SSP3), 'inequality' (SSP4), and 'fossil fuel intensive' development (SSP5) (Cross-Chapter Box 1.4, Figure 1) (O'Neill et al., 2017a). More specific information on the SSP framework and the assumptions underlying the SSPs will be provided in the IPCC WGIII report (WGIII, Chapter 3; see also Box SPM.1 in SRCCL (IPCC, 2019d)).

The SSP narratives and drivers were used to develop scenarios of energy use, air pollution control, land use and greenhouse gas (GHG) emissions developments using integrated assessment models (IAMs) (Riahi et al., 2017; Rogelj et al., 2018a). An IAM can derive multiple emission futures for each socio-economic development pathway, assuming no new mitigation policies or various levels of additional mitigation action (in the case of reference scenarios and mitigation scenarios, respectively (Riahi et al., 2017). By design, the evolution of drivers and emissions within the SSP scenarios do not take into account the effects of climate change.

The SSPX-Y scenarios and the RCP scenarios are categorized similarly, by reference to the approximate radiative forcing levels each one entails at the end of the 21st century. For example, the '1.9' in the SSP1-1.9 scenario stands for an approximate radiative forcing level of 1.9 W m^{-2} in 2100. The first number (X) in the 'SSPX-Y' acronym refers to one of the five shared socio-economic development pathways (Cross-Chapter Box 1.4, Figure 1; Table 1.4).

[START TABLE 1.4 HERE]

Table 1.4: Overview of different RCP and SSP acronyms as used in this report.

Scenario Acronym	Description
'**SSPX**' with X standing for the shared socioeconomic pathway family (1, 2, …, 5)	The shared socioeconomic pathway family, i.e., the socioeconomic developments with storylines regarding (among other things) GDP, population, urbanisation, economic collaboration, human and technological development projections that describe different future worlds in the absence of climate change and additional climate policy (O'Neill et al., 2014). The quantification of energy, land use and emission implications in those storylines is not part of the SSPX narratives, but follows in a second step in which their climate outcomes are defined. This second step is dependent upon the IAM that is used for this quantification (Riahi et al., 2017) (see SSPX-Y)
'**RCPY**' with Y	Representative Concentration Pathways (Moss et al., 2010; van Vuuren et al., 2011).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

standing for approximate radiative forcing level in 2100, at levels 2.6, 4.5, 6.0 or 8.5.	These are GHG concentrations (Meinshausen et al., 2011b) , aerosol emissions (Lamarque et al., 2011) and land use pattern time series (Hurtt et al., 2011) derived from several IAMs. The pathways were originally generated from specific sets of socio-economic drivers, but these are no longer considered. Instead, these RCP emission and concentration time series are used in combination with a range of socio-economic futures (see SSPX-RCPY). For example, the CMIP5 intercomparison (assessed in IPCC AR5) developed climate futures based on these emission and concentration pathways from the RCPs.
The SSP and RCP combination '**SSPX-RCPY**' with X and Y as above.	Combination of the SSP socioeconomic pathway X with climate futures stemming from GCMs, AOGCMs or Earth system model runs that used the RCPY. This combination is widely used in the impact literature assessed by WGII (see for example the Special Issue on SSPs by van Vuuren et al. (2014) and the large literature collection in the International Committee On New Integrated Climate change assessment Scenarios database (ICONICS, 2021). These SSPX-RCPY scenarios differ from the SSPX-Y group (below) in that the respective socio-economic futures (SSPXs) and emission and concentration futures (RCPYs) were developed separately before being used in combination.
'**SSPX-Y**' with X and Y as above.	SSPX-Y is the abbreviation for a scenario, where X is the numbering of the SSP socioeconomic family (1 to 5) that was used to develop the emission pathway, and the Y indicates the approximate radiative forcing value reached by the end of the century. The SSPX-Y scenarios span the nominal range from 1.9 to 8.5 W m^2. A range of different IAMs were used to quantify the SSPX-Y scenarios, but each IAM quantified both the scenario-economic futures (energy use, land use, population etc) and various emission futures within the same IAM modelling framework, thus enhancing the consistency between the socio-economic backgrounds and their resulting emission futures. In contrast, the SSPX-RCPY framework combines the SSP socio-economic futures and RCP emission and concentration futures at random (see above). For more details, see Section 1.6.1.1.

[END TABLE 1.4 HERE]

This SSP scenario categorisation, focused on end-of-century radiative forcing levels, reflects how scenarios were conceptualized until recently, namely, to reach a particular climate target in 2100 at the lowest cost and irrespective of whether the target was exceeded over the century. More recently, and in particular since the IPCC SR1.5 report focused attention on peak warming scenarios (Rogelj et al., 2018b), scenario development started to explicitly consider peak warming, cumulative emissions and the amount of net negative emissions (Rogelj et al., 2018b; Fujimori et al., 2019).

The SSP scenarios can be used for either emission- or concentration-driven model experiments (Cross-Chapter Box 1.4). ESMs can be run with emissions and concentrations data for GHGs and aerosols and land use or landcover maps and calculate levels of radiative forcing internally. The radiative forcing labels of the RCP and SSP scenarios, such as '2.6' in RCP2.6 or SSP1-2.6, are thus approximate labels for the year 2100 only. The actual global mean effective radiative forcing varies across ESMs due to different radiative transfer schemes, uncertainties in aerosol-cloud interactions and different feedback mechanisms, among other reasons. Nonetheless, using approximate radiative forcing labels is advantageous because it establishes a clear categorization of scenarios, with multiple climate forcings and different combinations in those scenarios summarized in a single number. The classifications according to cumulative carbon emissions (see Section 1.6.3) and global warming level (see Section 1.6.2 and Cross-Chapter Box 7.1 on emulators in Chapter 7) complement those forcing labels.

A key advance of the SSP scenarios relative to the RCPs is a wider span of assumptions on future air quality

ACCEPTED VERSION SUBJECT TO FINAL EDITS

mitigation measures, and hence emissions of short-lived climate forcers (SLCFs) (Rao et al., 2017; Lund et al., 2020). This allows for a more detailed investigation into the relative roles of GHG and SLCF emissions in future global and regional climate change, and hence the implications of policy choices. For instance, SSP1-2.6 builds on an assumption of stringent air quality mitigation policy, leading to rapid reductions in particle emissions, while SSP3-7.0 assumes slow improvements, with pollutant emissions over the 21st century comparable to current levels (Cross-Chapter Box 1.4, Figure 2, Chapter 6, Figure 6.19).

One limitation of the SSP scenarios used for CMIP6 and in this Report is that they reduce emissions from all the major ozone-depleting substances controlled under the Montreal Protocol (CFCs, halons, and hydrochlorofluorocarbons (HCFCs)) uniformly, rather than representing a fuller range of possible high and low emission futures (UNEP, 2016). Hydrofluorocarbon (HFC) emissions, on the other hand, span a wider range within the SSPs than in the RCPs (Cross-Chapter Box 1.4, Figure 2).

The SSP scenarios and previous RCP scenarios are not directly comparable. First, the gas-to-gas compositions differ; for example, the SSP5-8.5 scenario has higher CO_2 concentrations but lower methane concentrations compared to RCP8.5. Second, the projected 21st-century trajectories may differ, even if they result in the same radiative forcing by 2100. Third, the overall effective radiative forcing (see Chapter 7) may differ, and tends to be higher for the SSPs compared to RCPs that share the same nominal stratospheric-temperature adjusted radiative forcing label. The stratospheric-temperature adjusted radiative forcings of the SSPs and RCPs, however, remain relatively close, at least by 2100 (Tebaldi et al., 2021). In summary, differences in, for example, CMIP5 RCP8.5 and CMIP6 SSP5-8.5 ESM outputs, are partially due to different scenario characteristics rather than different ESM characteristics only (Chapter 4, Section 4.6.2).

When investigating various mitigation futures, WGIII goes beyond the core set of SSP scenarios assessed in WGI (SSP1-1.9, SSP1-2.6, etc.) to consider the characteristics of more than 1000 scenarios (see Cross-Chapter Box 7.1 in Chapter 7). In addition, while staying within the framework of socio-economic development pathways (SSP1 to SSP5), WGIII also considers various mitigation possibilities through so-called illustrative pathways (IPs). These illustrative pathways help to highlight key narratives in the literature concerning various technological, social and behavioral options for mitigation, various timings for implementation, or varying emphasis on different GHG and land use options. Just as with the SSPX-Y scenarios considered in this report, these illustrative pathways can be placed in relation to the matrix of SSP families and approximate radiative forcing levels in 2100 (see Cross-Chapter Box 1.4, Figure 1 and Working Group III, Chapter 3).

No likelihood is attached to the scenarios assessed in this report, and the feasibility of specific scenarios in relation to current trends is best informed by the WGIII contribution to AR6. In the scenario literature, the plausibility of the high emissions levels underlying scenarios such as RCP8.5 or SSP5-8.5 has been debated in light of recent developments in the energy sector. (see Section 1.6.1.4).

[START CROSS CHAPTER BOX 1.4 HERE]

Cross-Chapter Box 1.4: The SSP scenarios as used in Working Group I

Contributing Authors: Jan Fuglestvedt (Norway), Celine Guivarch (France), Chris Jones (UK), Malte Meinshausen (Australia/Germany), Zebedee Nicholls (Australia), Gian-Kasper Plattner (Switzerland), Keywan Riahi (Austria), Joeri Rogelj (UK/Belgium), Sophie Szopa (France), Claudia Tebaldi (USA/Italy), Anne-Marie Treguier (France), and Detlef van Vuuren (Netherlands)

The new nine SSP emission and concentration scenarios (SSP1-1.9 to SSP5-8.5; Cross-Chapter Box 1.4, Table 1) offer unprecedented detail of input data for climate model simulations. They allow for a more comprehensive assessment of climate drivers and responses than has previously been available, in particular because some of the scenarios' time series, e.g., pollutants, emissions or changes in land use and land cover, are more diverse in the SSP scenarios than in the RCPs used in AR5 (e.g., Chuwah et al., 2013) (Cross-Chapter Box 1.4, Figure 2).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

The core set of five SSP scenarios SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 was selected in this Report to align with the objective that the new generation of SSP scenarios should fill certain gaps identified in the RCPs. For example, a scenario assuming reduced air pollution control and thus higher aerosol emissions was missing from the RCPs. Likewise, nominally the only 'no-additional-climate-policy' scenario in the set of RCPs was RCP8.5. The new SSP3-7.0 'no-additional-climate-policy' scenario fills both these gaps. A very strong mitigation scenario in line with the 1.5°C goal of the Paris Agreement was also missing from the RCPs, and the SSP1-1.9 scenario now fills this gap, complementing the other strong mitigation scenario SSP1-2.6. The five core SSPs were also chosen to ensure some overlap with the RCP levels for radiative forcing at the year 2100 (specifically 2.6, 4.5, and 8.5) (O'Neill et al., 2016; Tebaldi et al., 2021), although effective radiative forcings are generally higher in the SSP scenarios compared to the equivalently-named RCP pathways (Cross-Chapter Box 1.4, Figure 1; Chapter 4, Section 4.6.2). In theory, running scenarios with similar radiative forcings would permit analysis of the CMIP5 and CMIP6 outcomes for pairs of scenarios (e.g., RCP8.5 and SSP5-8.5) in terms of varying model characteristics rather than differences in the underlying scenarios. In practice, however, there are limitations to this approach (Section 1.6.1.1 and Chapter 4, Section 4.6.2).

[START Cross-Chapter Box 1.4, FIGURE 1 HERE]

Cross-Chapter Box 1.4, Figure 1: The SSP scenarios used in this report, their indicative temperature evolution and radiative forcing categorization, and the five socio-economic storylines upon which they are built. The core set of scenarios used in this report, i.e., SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5, is shown together with an additional four SSPs that are part of ScenarioMIP, as well as previous RCP scenarios. In the left panel, the indicative temperature evolution is shown (adapted from Meinshausen et al., 2020). The black stripes on the respective scenario family panels on the left side indicate a larger set of IAM-based SSP scenarios that span the scenario range more fully, but are not used in this report. The SSP-radiative forcing matrix is shown on the right, with the SSP socioeconomic narratives shown as columns and the indicative radiative forcing categorisation by 2100 shown as rows. Note that the descriptive labels for the five SSP narratives refer mainly to the reference scenario futures without additional climate policies. For example, SSP5 can accommodate strong mitigation scenarios leading to net zero emissions; these do not match a 'fossil-fueled development' label. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END Cross-Chapter Box 1.4, FIGURE 1 HERE]

[START Cross-Chapter Box 1.4, TABLE 1 HERE]

Cross-Chapter Box 1.4, Table 1: Overview of SSP scenarios used in this report. The middle column briefly describes the SSP scenarios and the right column indicates the previous RCP scenarios that most closely match that SSP's assessed global-mean temperatures (GSAT) trajectory. RCP scenarios are generally found to result in larger modelled warming for the same nominal radiative forcing label (Chapter 4, Section 4.6.2.2). The five core SSP scenarios used most commonly in this report are highlighted in bold. Further SSP scenarios are used where they allow assessment of specific aspects, e.g., air pollution policies in Chapter 6 (SSP3-7.0-lowNTCF). RCPs are used in this report wherever the relevant scientific literature makes substantial use of regional or domain-specific model output that is based on these previous RCP pathways, such as sea level rise projections in Chapter 9 (Section 9.6.3.1) or regional climate aspects in Chapters 10 and 12. See Chapter 4 (Section 4.3.4) for the GSAT assessment for the SSP scenarios and Section 4.6.2.2 for a comparison between SSPs and RCPs in terms of both radiative forcing and global surface temperature.

SSPX-Y scenario	Description from an emission / concentration and temperature perspective (Chapter 4, Table 4.2)	Closest RCP scenarios
SSP1-1.9	Holds warming to approximately 1.5°C above 1850-1900 in 2100 after slight overshoot (median) and implied net zero	Not available. No equivalently low RCP scenario exists.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

	CO_2 emissions around the middle of the century.	
SSP1-2.6	Stays below 2.0°C warming relative to 1850-1900 (median) with implied net zero emissions in the second half of the century.	RCP2.6, although RCP2.6 might be cooler for the same model settings.
SSP4-3.4	A scenario in between SSP1-2.6 and SSP2-4.5 in terms of end-of-century radiative forcing. It does not stay below 2.0°C in most CMIP6 runs (Chapter 4) relative to 1850-1900.	No 3.4 level of end-of-century radiative forcing was available in the RCPs. Nominally SSP4-3.4 sits between RCP 2.6 and RCP 4.5, although SSP4-3.4 might be more similar to RCP4.5. Also, in the early decades of the 21st century, SSP4-3.4 is close to RCP6.0, which featured lower radiative forcing than RCP4.5 in the first decades of the 21st century.
SSP2-4.5	Scenario approximately in line with the upper end of aggregate NDC emission levels by 2030 (see Section 1.2.2 and Chapter 4, Section 4.3; SR1.5, (IPCC, 2018) , Box 1). SR1.5 assessed temperature projections for NDCs to be between 2.7 and 3.4°C by 2100 (Section 1.2.2; SR1.5 (IPCC, 2018); Cross-Chapter Box 11 in Chapter 11), corresponding to the upper half of projected warming under SSP2-4.5 (Chapter 4). New or updated NDCs by the end of 2020 did not significantly change the emissions projections up to 2030, although more countries adopted 2050 net zero targets in line with SSP1-1.9 or SSP1-2.6. The SSP2-4.5 scenario deviates mildly from a 'no-additional-climate-policy' reference scenario, resulting in a best-estimate warming around 2.7°C by the end of the 21st century relative to 1850-1900 (Chapter 4).	RCP4.5 and, until 2050, also RCP6.0. Forcing in the latter was even lower than RCP4.5 in the early decades of the 21st century.
SSP4-6.0	The end-of-century nominal radiative forcing level of 6.0 W/m^2 can be considered a 'no-additional-climate-policy' reference scenario, under SSP1 and SSP4 socioeconomic development narratives.	RCP6.0 is nominally closest in the second half of the century, although global mean temperatures are estimated to be generally lower in RCPs compared to SSPs. Furthermore, RCP6.0 features lower warming than SSP4-6.0, as it has very similar temperature projections compared to the nominally lower RCP4.5 scenario in the first half of the century.
SSP3-7.0	A medium to high reference scenario resulting from no additional climate policy under the SSP3 socioeconomic development narrative. SSP3-7.0 has particularly high non-CO_2 emissions, including high aerosols emissions.	In between RCP6.0 and RCP8.5, although SSP3-7.0 non-CO_2 emissions and aerosols are higher than in any of the RCPs.
SSP3-7.0-lowNTCF	A variation of the medium to high reference scenario SSP3-7.0 but with	SSP3-7.0-lowNTCF is between RCP6.0 and RCP8.5, as RCP scenarios generally

ACCEPTED VERSION SUBJECT TO FINAL EDITS

	mitigation of CH_4 and/or short-lived species such as black carbon and other short-lived climate forcers (SLCF). Note that variants of SSP3-7.0-lowNTCF differ in terms of whether methane emissions are reduced[9] (Chapter 4, Section 4.4 and Chapter 6, Section 6.6).	incorporated a narrow and comparatively low level of SLCF emissions across the range of RCPs.
SSP5-3.4 OS (Overshoot)	A mitigation-focused variant of SSP5-8.5 that initially follows unconstrained emission growth in a fossil-intensive setting until 2040 and then implements the largest net negative CO_2 emissions of all SSP scenarios in the second half of 21st century to reach SSP1-2.6 forcing levels in the 22nd century. Used to consider reversibility and strong overshoot scenarios in, e.g., Chapters 4 and 5.	Not available. Initially, until 2040, similar to RCP8.5.
SSP5-8.5	A high reference scenario with no additional climate policy. Emission levels as high as SSP5-8.5 are not obtained by Integrated Assessment Models (IAMs) under any of the SSPs other than the fossil fueled SSP5 socioeconomic development pathway.	RCP8.5, although CO_2 emissions under SSP5-8.5 are higher towards the end of the century (Cross-Chapter Box 1.4, Figure 2). Methane emissions under SSP5-8.5 are lower than under RCP 8.5. When used with the same model settings, SSP5-8.5 may result in slightly higher temperatures than RCP8.5 (Chapter 4, Section 4.6.2).

[END Cross-Chapter Box 1.4, TABLE 1 HERE]

In contrast to stylized assumptions about the future evolution of emissions (e.g., a linear phase-out from year A to year B), these SSP scenarios are the result of a detailed scenario generation process (see Sections 1.6.1.1 and 1.6.1.2). While IAMs produce internally-consistent future emission time series for CO_2, CH_4, N_2O, and aerosols for the SSP scenarios (Riahi et al., 2017; Rogelj et al., 2018a), these emission scenarios are subject to several processing steps for harmonisation (Gidden et al., 2018) and in-filling (Lamboll et al., 2020), before also being complemented by several datasets so that ESMs can run these SSPs (Durack et al., 2018; Tebaldi et al., 2021). Although five scenarios are the primary focus of WGI, a total of nine SSP scenarios have been prepared with all the necessary detail to drive the ESMs as part of the CMIP6 (Cross-Chapter Box 1.4, Figure 1 and Table 2).

[START Cross-Chapter Box 1.4, TABLE 2 HERE]

Cross-Chapter Box 1.4, Table 2: Overview of key climate forcer datasets used as input by ESMs for historical and future SSP scenario experiments. The data is available from the Earth System Grid Federation (ESGF, 2021) described in Eyring et al. (2016).

[9] The AerChemMIP variant of SSP3-7.0-lowNTCF (Collins et al., 2017) only reduced aerosol and ozone precursors compared to SSP3-7.0, not methane. The SSP3-7.0-lowNTCF variant by the Integrated Assessment Models also reduced methane emissions (Gidden et al., 2019), which creates differences between SSP3-7.0-lowNTCF and SSP3-7.0 also in terms of methane concentrations and some fluorinated gas concentrations that have OH related sinks (Meinshausen et al., 2020).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Climate Forcer	Description
CO_2 emissions (emission-driven runs only)	Harmonized historical and future gridded emissions of anthropogenic CO_2 emissions (Hoesly et al., 2018; Gidden et al., 2019) are used instead of the prescribed CO_2 concentrations. See Chapter 4 (Section 4.3.1).
Historical and future greenhouse gas concentrations	Greenhouse gas surface air mole fractions of 43 species, including CO_2, CH_4, N_2O, HFCs, PFCs, halons, HCFCs, CFCs, SF_6, NF_3, including latitudinal gradients and seasonality from year 1 to 2500 (Meinshausen et al., 2017, 2020)
Land use change and management patterns	Globally gridded land use and land cover change datasets (Hurtt et al., 2020; Ma et al., 2020b)
Biomass burning emissions	Historical fire-related gridded emissions, including SO_2, NO_x, CO, BC, OC, NH_3, NMVOCs, relevant to concentration-driven historical and future SSP scenario runs (van Marle et al., 2017).
Stratospheric and tropospheric ozone	Historical and future ozone dataset, also with total column ozone (CCMI, 2021).
Reactive gas emissions	Gridded global anthropogenic emissions of reactive gases and aerosol precursors, including CO, SO_x, CH_4, NO_x, NMVOCs, or NH_3 (Hoesly et al., 2018; Feng et al., 2020)
Solar forcing	Radiative and particle input of solar variability from 1850 through to 2300 (Matthes et al., 2017). Future variations in solar forcing also reflect long-term multi-decadal trends.
Volcanic forcing	Historical stratospheric aerosol climatology (Thomason et al., 2018), with the mean stratospheric volcanic aerosol prescribed in future projections.

[END Cross-Chapter Box 1.4, TABLE 2 HERE]

ESMs are driven by either emission or concentration scenarios. Inferring concentration changes from emission time series requires using carbon cycle and other gas cycle models. To aid comparability across ESMs, and in order to allow participation of ESMs that do not have coupled carbon and other gas cycles models in CMIP6, most of the CMIP6 ESM experiments are so-called 'concentration-driven' runs, with concentrations of CO_2, CH_4, N_2O and other well-mixed GHGs prescribed in conjunction with aerosol emissions, ozone changes and effects from human-induced land cover changes that may be radiatively active via albedo changes (Cross-Chapter Box 1.4, Figure 2). In these concentration-driven climate projections, the uncertainty in projected future climate change resulting from our limited understanding of how the carbon cycle and other gas cycles will evolve in the future is not captured. For example, when deriving the default concentrations for these scenarios, permafrost and other carbon cycle feedbacks are considered using default settings, with a single time series prescribed for all ESMs (Meinshausen et al., 2020). Thus, associated uncertainties (Joos et al., 2013; Schuur et al., 2015) are not considered.

The so-called 'emission-driven' experiments (Jones et al., 2016b) use the same input datasets as concentration-driven ESM experiments, except that they use CO_2 emissions rather than concentrations (Chapter 4, Section 4.3.1; Chapter 5). In these experiments, atmospheric CO_2 concentrations are calculated internally using the ESM interactive carbon cycle module and thus differ from the prescribed default CO_2 concentrations used in the concentration-driven runs. In the particular case of SSP5-8.5, the emission-driven runs are assessed to add no significant additional uncertainty to future global surface air temperature (GSAT) projections (Chapter 4, Section 4.3.1). However, generally, when assessing uncertainties in future climate

ACCEPTED VERSION SUBJECT TO FINAL EDITS

projections, it is important to consider which elements of the cause-effect chain from emissions to the resulting climate change are interactively included as part of the model projections, and which are externally prescribed using default settings.

[START Cross-Chapter Box 1.4, FIGURE 2 HERE]

Cross-Chapter Box 1.4, Figure 2: Comparison between the Shared Socio-economic Pathways (SSP) scenarios and the Representative Concentration Pathway (RCP) scenarios in terms of their CO_2, CH_4 and N_2O atmospheric concentrations (panels a-c), and their global emissions (panels d-o). Also shown are gridded emission differences for sulfur (panel p) and black carbon (panel q) for the year 2000 between the input emission datasets that underpinned the CMIP5 and CMIP6 model intercomparisons. Historical emission estimates are provided in black in panels d to o. The range of concentrations and emissions investigated under the RCP pathways is grey shaded. Panels p and q adapted from Figure 7 in Hoesly et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

1.6.1.2 Scenario generation process for CMIP6

The scenario generation process involves research communities linked to all three IPCC Working Groups (Figure 1.27). It generally starts in the scientific communities associated with WGII and WGIII with the definition of new socio-economic scenario storylines (IPCC, 2000; O'Neill et al., 2014) that are quantified in terms of their drivers, i.e., GDP, population, technology, energy and land use and their resulting emissions (Riahi et al., 2017). Then, numerous complementation and harmonisation steps are necessary for datasets within the WGI and WGIII science communities, including gridding emissions of anthropogenic short-lived forcers, providing open biomass burning emission estimates, preparing land use patterns, aerosol fields, stratospheric and tropospheric ozone, nitrogen deposition datasets, solar irradiance and aerosol optical property estimates, and observed and projected greenhouse gas concentration time series (documented for CMIP6 through input4mips; Durack et al., 2018; Cross-Chapter Box 1.4, Table 2).

Once these datasets are completed, ESMs are run in coordinated model intercomparison projects in the WGI science community, using standardized simulation protocols and scenario data. The most recent example of such a coordinated effort is the CMIP6 exercise (Eyring et al., 2016; see also Section 1.5.4) with, in particular, ScenarioMIP (O'Neill et al., 2016). The WGI science community feeds back climate information to WGIII via climate emulators (Cross-Chapter Box 7.1 in Chapter 7) that are updated and calibrated with the ESMs' temperature responses and other lines of evidence. Next, this climate information is used to compute several high-level global climate indicators (e.g., atmospheric concentrations, global temperatures) for a much wider set of hundreds of scenarios that are assessed as part of IPCC WGIII assessment (WGIII Annex C). The outcomes from climate models run under the different scenarios are then used to calculate the evolution of climatic impact-drivers (Chapter 12), and utilized by impact researchers together with exposure and vulnerability information, in order to characterize risk from future climate change to human and natural systems. The climate impacts associated with these scenarios or different warming levels are then assessed as part of WGII reports (Figure 1.27).

[START FIGURE 1.27 HERE]

Figure 1.27: A simplified illustration of the scenario generation process that involves the scientific communities represented in the three IPCC Working Groups. The circular set of arrows at the top indicate the main set of models and workflows used in that scenario generation process, with the lower level indicating the datasets.

[END FIGURE 1.27 HERE]

1.6.1.3 History of scenarios within the IPCC

Scenario modelling experiments have been a core element of physical climate science since the first transient simulations with a General Circulation Model in 1988 (Hansen et al., 1988; see Section 1.3). Scenarios and modelling experiments assessed in IPCC reports have evolved over time, which provides a 'history of how the future was seen'. The starting time for the scenarios moves as actual emissions supersede earlier emission assumptions, while new scientific insights into the range of plausible population trends, behavioural changes and technology options and other key socioeconomic drivers of emissions also emerge (see WGIII; Legget, 1992; IPCC, 2000; Moss et al., 2010; Riahi et al., 2017). Many different sets of climate projections have been produced over the past several decades, using different sets of scenarios. Here, we compare those earlier scenarios against the most recent ones.

Climate science research involving scenarios necessarily follows a series of consecutive steps (see Figure 1.27). As each step waits for input from the preceding one, delays often occur that result in the impact literature basing its analyses on earlier scenarios than those most current in the climate change mitigation and climate system literature. It is hence important to provide an approximate comparison across the various scenario generations (Figure 1.28; Cross-Chapter Box 1.4, Table 1; Chapter 4).

[START FIGURE 1.28 HERE]

Figure 1.28: Comparison of the range of fossil and industrial CO_2 emissions from scenarios used in previous assessments up to AR6. Previous assessments are the IS92 scenarios from 1992 (top panel), the Special Report on Emissions Scenarios (SRES) scenarios from the year 2000 (second panel), the Representative Concentration Pathway (RCP) scenarios designed around 2010 (third panel) and the Shared Socio-economic Pathways (SSP) scenarios (second bottom panel). In addition, historical emissions are shown (black line) (Chapter 5, Figure 5.5); a more complete set of scenarios is assessed in SR1.5 (bottom panel) (Huppmann et al., 2018). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.28 HERE]

The first widely used set of IPCC emission scenarios was the IS92 scenarios in 1992 (Leggett et al., 1992). Apart from reference scenarios, IS92 also included a set of stabilisation scenarios, the so-called 'S' scenarios. Those 'S' pathways were designed to lead to CO_2 stabilisation levels such as 350 ppm or 450 ppm. By 1996, those latter stabilisation levels were complemented in the scientific literature by alternative trajectories that assumed a delayed onset of climate change mitigation action (Figure 1.28; Wigley et al., 1996).

By 2000, the IPCC Special Report on Emission Scenarios (SRES) produced the SRES scenarios (IPCC, 2000), albeit without assuming any climate-policy-induced mitigation. The four broad groups of SRES scenarios (scenario 'families') A1, A2, B1 and B2 were the first scenarios to emphasize socio-economic scenario storylines, and also first to emphasize other greenhouse gases, land use change and aerosols. Represented by three scenarios for the high-growth A1 scenario family, those 6 SRES scenarios (A1FI, A1B, A1T, A2, B1, and B2) can still sometimes be found in today's climate impact literature. The void of missing climate change mitigation scenarios was filled by a range of community exercises, including the so-called post-SRES scenarios (Swart et al., 2002).

The RCP scenarios (van Vuuren et al., 2011) then broke new ground by providing low emission pathways that implied strong climate change mitigation including an example with negative CO_2 emissions on a large scale, namely RCP2.6. As shown in Figure 1.28, the upper end of the scenario range has not substantially

ACCEPTED VERSION SUBJECT TO FINAL EDITS

shifted. Building on the SRES multi-gas scenarios, the RCPs include time series of emissions and concentrations of the full suite of greenhouse gases and aerosols and chemically active gases, as well as land use and land cover (Moss et al., 2010). The word 'representative' signifies that each RCP is only one of many possible scenarios that would lead to the specific radiative forcing characteristics. The term pathway emphasizes that not only the long-term concentration levels are of interest, but also the trajectory taken over time to reach that outcome (Moss et al., 2010). RCPs usually refer to the concentration pathway extending to 2100, for which IAMs produced corresponding emission scenarios. Four RCPs produced from IAMs were selected from the published literature and are used in AR5 as well as in this report, spanning approximately the range from below 2°C warming to high (>4°C) warming best-estimates by the end of the 21st century: RCP2.6, RCP4.5 and RCP6.0 and RCP8.5 (Cross-Chapter Box 1.4, Table 1). Extended Concentration Pathways (ECPs) describe extensions of the RCPs from 2100 to 2300 that were calculated using simple rules generated by stakeholder consultations; these do not represent fully consistent scenarios (Meinshausen et al., 2011b).

By design, the RCP emission and concentration pathways were originally developed using particular socio-economic development pathways, but those are no longer considered (Moss et al., 2010). The different levels of emissions and climate change represented in the RCPs can hence be explored against the backdrop of different socio-economic development pathways (SSP1 to SSP5) (Section 1.6.1.1; Cross-Chapter Box 1.4). This integrative SSP-RCP framework ('SSPX-RCPY' in Table 1.4) is now widely used in the climate impact and policy analysis literature (e.g., ICONICS, 2021; Green et al., 2020; O'Neill et al., 2020), where climate projections obtained under the RCP scenarios are analysed against the backdrop of various SSPs. Considering various levels of future emissions and climate change for each socio-economic development pathway was an evolution from the previous SRES framework (IPCC, 2000), in which socio-economic and emission futures were closely aligned.

The new set of scenarios (SSP1-1.9 to SSP5-8.5) now features a higher top level of CO_2 emissions (SSP5-8.5 compared to RCP8.5), although the most significant change is again the addition of a very low climate change mitigation scenario (SSP1-1.9, compared to the previous low scenario, RCP2.6). Also, historically, none of the previous scenario sets featured a scenario that involves a very pronounced peak-and-decline emissions trajectory, but SSP1-1.9 does so now. The full set of nine SSP scenarios now includes a high aerosol emission scenario (SSP3-7.0). The RCPs featured more uniformly low aerosol trajectories across all scenarios (Cross-Chapter Box 1.4, Figure 2). More generally, the SSP scenarios feature a later peak of global emission for the lower scenarios, simply as a consequence of historical emissions not having followed the trajectory projected by previous low scenarios (Figure 1.28).

Over the last decades, discussions around scenarios have often focussed on whether recent trends make certain future scenarios more or less probable or whether all scenarios are too high or too low. When the SRES scenarios first appeared, the debate was often whether the scenarios were overestimating actual world emissions developments (e.g., Castles and Henderson, 2003). With the strong emissions increase throughout the 2000s, that debate then shifted towards the question of whether the lower future climate change mitigation scenarios were rendered unfeasible (Pielke et al., 2008; van Vuuren and Riahi, 2008). Historical emissions over 2000 to 2010 approximately track the upper half of SRES and RCP projections (Figure 1.28). More generally, the global fossil and industrial CO_2 emissions of recent decades tracked approximately the middle of the projected scenario ranges (see Fig 1.28), although with regional differences (Pedersen et al., 2020).

1.6.1.4 The likelihood of reference scenarios, scenario uncertainty and storylines

In general, no likelihood is attached to the scenarios assessed in this Report. The use of different scenarios for climate change projections allows to explore 'scenario uncertainty' (Collins et al., 2013; SR1.5; see also Section 1.4.4). Scenario uncertainty is fundamentally different from geophysical uncertainties, which result from limitations in the understanding and predictability of the climate system (Smith and Stern, 2011). In scenarios, by contrast, future emissions depend to a large extent on the collective outcome of choices and processes related to population dynamics and economic activity, or on choices that affect a given activity's

ACCEPTED VERSION SUBJECT TO FINAL EDITS

energy and emissions intensity (Jones, 2000; Knutti et al., 2008; Kriegler et al., 2012; van Vuuren et al., 2014). Even if identical socio-economic futures are assumed, the associated future emissions still face uncertainties, since different experts and model frameworks diverge in their estimates of future emission ranges (Ho et al., 2019).

When exploring various climate futures, scenarios with no, or no additional, climate policies are often referred to as 'baseline' or 'reference scenarios' (Section 1.6.1.1; Annex VII: Glossary). Among the five core scenarios used most in this report, SSP3-7.0 and SSP5-8.5 are explicit 'no-climate-policy' scenarios (Gidden et al., 2019; Cross-Chapter Box 1.4, Table 1), assuming a carbon price of zero. These future 'baseline' scenarios are hence counterfactuals that include less climate policies compared to 'business-as-usual' scenarios – given that 'business-as-usual' scenarios could be understood to imply a continuation of existing climate policies. Generally, future scenarios are meant to cover a broad range of plausible futures, due for example to unforeseen discontinuities in development pathways (Raskin and Swart, 2020), or to large uncertainties in underlying long-term projections of economic drivers (Christensen et al., 2018). However, the likelihood of high emission scenarios such as RCP8.5 or SSP5-8.5 is considered low in light of recent developments in the energy sector (Hausfather and Peters, 2020a, 2020b). Studies that consider possible future emission trends in the absence of additional climate policies, such as the recent IEA 2020 World Energy Outlook 'stated policy' scenario (International Energy Agency, 2020), project approximately constant fossil and industrial CO_2 emissions out to 2070, approximately in line with the medium RCP4.5, RCP6.0 and SSP2-4.5 scenarios (Hausfather and Peters, 2020b) and the 2030 global emission levels that are pledged as part of the Nationally Determined Contributions (NDCs) under the Paris Agreement (Section 1.2.2; (Fawcett et al., 2015; Rogelj et al., 2016; UNFCCC, 2016; IPCC, 2018). On the other hand, the default concentrations aligned with RCP8.5 or SSP5-8.5 and resulting climate futures derived by ESMs could be reached by lower emission trajectories than RCP8.5 or SSP5-8.5. That is because the uncertainty range on carbon-cycle feedbacks includes stronger feedbacks than assumed in the default derivation of RCP8.5 and SSP5-8.5 concentrations (Ciais et al., 2013; Friedlingstein et al., 2014; Booth et al., 2017; see also Chapter 5, Section 5.4).

To address long-term scenario uncertainties, scenario storylines (or 'narratives') are often used (Rounsevell and Metzger, 2010; O'Neill et al., 2014) (see Section 1.4.4 for a more general discussion on 'storylines' also covering 'physical climate storylines'). Scenario storylines are descriptions of a future world, and the related large-scale socio-economic development path towards that world that are deemed plausible within the current state of knowledge and historical experience (WGIII; Section 1.2.3). Scenario storylines attempt to 'stimulate, provoke, and communicate visions of what the future could hold for us' (Rounsevell and Metzger, 2010) in settings where either limited knowledge or inherent unpredictability in social systems prevent a forecast or numerical prediction. Scenario storylines have been used in previous climate research, and they are the explicit or implicit starting point of any scenario exercise, including for the SRES scenarios (IPCC, 2000) and the SSPs (e.g., O'Neill et al., 2017a).

Recent technological or socio-economic trends might be informative for bounding near-term future trends, for example, if technological progress renders a mitigation technology cheaper than previously assumed. However, short-term emission trends alone do not generally rule out an opposite trend in the future (van Vuuren et al., 2010). The ranking of individual RCP emission scenarios from the IAMs with regard to emission levels is different for different time horizons, e.g., 2020 versus longer-term emission levels; For example, the strongest climate change mitigation scenario RCP2.6 was in fact the second highest CO_2 emission scenario (jointly with RCP4.5) before 2020 in the set of RCPs and the strong global emission decline in RCP2.6 only followed after 2020. Implicitly, this scenario feature was cautioning against the assumption that short-term trends predicate particular long-term trajectories. This is also the case in relation to the COVID-19 related drop in 2020 emissions. Potential changes in underlying drivers of emissions, such as those potentially incentivised by COVID-19 recovery stimulus packages, are more significant for longer-term emissions than the short-term deviation from recent emission trends (Cross-Chapter Box 6.1 on COVID-19 in Chapter 6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

1.6.2 Global warming levels

The global mean surface temperature change, or 'global warming level' (GWL), is a 'dimension of integration' that is highly relevant across scientific disciplines and socioeconomic actors. First, global warming levels relative to pre-industrial conditions are the quantity in which the 1.5°C and 'well below 2°C' Paris Agreement goals were formulated. Second, global mean temperature change has been found to be nearly-linearly related to a number of regional climate effects (Mitchell et al., 2000; Mitchell, 2003; Tebaldi and Arblaster, 2014; Seneviratne et al., 2016; Li et al., 2020; Seneviratne and Hauser, 2020). Even where non-linearities are found, some regional climate effects can be considered to be almost scenario-independent for a given level of warming (Cross-Chapter Box 11.1 in Chapter 11; Chapter 4, Sections 4.2.4 and 4.6.1; Chapter 8, Section 8.5.3; Chapter 10, Section 10.4.3.1). Finally, the evolution of aggregated impacts with warming levels has been widely used and embedded in the assessment of the 'Reasons for Concern' (RFC) in IPCC WGII (Smith et al., 2009; IPCC, 2014a). The RFC framework was further expanded in SR1.5 (2018), SROCC (2019) and SRCCL (2019) by explicitly describing the differential impacts of half-degree warming steps (cf. King et al., 2017) (Section 1.4.4; Cross-Chapter Box 12.1 in Chapter 12).

In this Report, the term 'global warming level' refers to the categorisation of global and regional climate change, associated impacts, emission and concentration scenarios by global mean surface temperature relative to 1850-1900, which is the period used as a proxy for pre-industrial levels (see Cross-Chapter Box 11.1 in Chapter 11). By default, GWLs are expressed as global surface air temperature (GSAT; see Section 1.4.1; Cross-Chapter Box 2.3 in Chapter 2).

As the SR1.5 concluded, even half-degree global mean temperature steps carry robust differences in climate impacts (see SR1.5,IPCC, 2018; Schleussner et al., 2016a; Wartenburger et al., 2017; see also Chapter 11). This Report adopts half-degree warming levels which allows integration within and across the three WGs for climate projections, impacts, adaptation challenges and mitigation challenges. The core set of - GWLs 1.5, 2.0, 3.0 and 4.0°C - are highlighted (Chapters 4, 8, 11, 12 and the Atlas). Given that much impact analysis is based on previous scenarios, i.e., RCPs or SRES, and climate change mitigation analysis is based on new emission scenarios in addition to the main SSP scenarios, these global warming levels assist in the comparison of climate states across scenarios and in the synthesis across the broader literature.

The transient and equilibrium states of certain global warming levels can differ in their climate impacts (IPCC, 2018; King et al., 2020). Climate impacts in a 'transient' world relate to a scenario in which the world is continuing to warm. On the other hand, climate impacts at the same warming levels can also be estimated from equilibrium states after a (relatively) short-term stabilisation by the end of the 21st century or at a (near-) equilibrium state after a long-term (multi-decadal to multi-millennial) stabilisation. Different methods to estimate these climate states come with challenges and limitations (Chapter 4, Section 4.6.1; Cross-Chapter Box 11.1 in Chapter 11). First, information can be drawn from GCM or ESM simulations that 'pass through' the respective warming levels (as used and demonstrated in the Interactive Atlas to this report), also called 'epoch' or 'time-shift' approaches (Chapter 4, Sections 4.2.4 and 4.6.1) (Herger et al., 2015; James et al., 2017; Tebaldi and Knutti, 2018). Information from transient simulations can also be used through an empirical scaling relationship (Seneviratne et al., 2016, 2018; Wartenburger et al., 2017) or using 'time sampling' approaches, as described in James et al. (2017). Second, information can be drawn from large ESM ensembles with prescribed SST at particular global warming levels (Mitchell et al., 2017), although an underrepresentation of variability can arise when using prescribed SST temperatures (Fischer et al., 2018a).

In order to fully derive climate impacts, warming levels will need to be complemented by additional information, such as their associated CO_2 concentrations (e.g., fertilization or ocean acidification), composition of the total radiative forcing (aerosols vs greenhouse gases, with varying regional distributions) or socioeconomic conditions (e.g., to estimate societal impacts). More fundamentally, while a global warming level is a good proxy for the state of the climate (Cross-Chapter Box 11.1 in Chapter 11), it does not uniquely define a change in global or regional climate state. For example, regional precipitation responses depend on the details of the individual forcing mechanisms that caused the change (Samset et al., 2016), on whether the temperature level is stabilized or transient (King et al., 2020; Zappa et al., 2020), on

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the vertical structure of the troposphere (Andrews et al., 2010), and, in particular, on the global distribution of atmospheric aerosols (Frieler et al., 2012). Another aspect is how Earth system components with century to millennial response timescales, such as long-term sea level rise or permafrost thaw, are affected by global mean warming. For example, sea level rise 50 years after a 1°C warming will be lower than sea level rise 150 years after that same 1°C warming (Chapter 9).

Also, forcing or response patterns that vary in time can create differences in regional climates for the same global mean warming level, or can create non-linearities when scaling patterns from one warming level to another (King et al., 2018), depending on whether near-term transient climate, end of the century, equilibrium climate or climate states after an initial overshoot are considered.

In spite of these challenges, and thanks to recent methodological advances in quantifying or overcoming them, global warming levels provide a robust and useful integration mechanism. They allow knowledge from various domains within WGI and across the three WGs to be integrated and communicated (Cross Chapter Box 11.1). In this report, Chapters 4, 8, 11, 12 and the Atlas provide information specific to certain warming levels, highlighting the regional differences, but also the approximate scalability of regional climate change, that can arise from even a 0.5°C shift in global-mean temperatures. Furthermore, building on WGI insights into physical climate system responses (Cross-Chapter Box 7.1 in Chapter 7), WGIII will use peak and end-of-century global warming levels to classify a broad set of scenarios.

1.6.3 Cumulative CO_2 emissions

The WGI AR5 (IPCC, 2013a) and the SR1.5 (IPCC, 2018) highlighted the near-linear relationship between cumulative carbon emissions and global mean warming (Section 1.3; Section 5.5). This implies that continued CO_2 emissions will cause further warming and changes in all components of the climate system, independent of any specific scenario or pathway. This is captured in the TCRE concept, which relates CO_2-induced global mean warming to cumulative carbon emissions (Chapter 5). This Report thus uses cumulative CO_2 emissions to compare the climate response across scenarios, and to categorise emission scenarios (Figure 1.29). The advantage of using cumulative CO_2 emissions is that it is an inherent emission scenario characteristic rather than an outcome of the scenario-based projections, where uncertainties in the cause-effect chain from emissions to atmospheric concentrations to temperature change are important.

There is also a close relationship between cumulative total greenhouse gas emissions and cumulative CO_2 emissions for scenarios in the SR1.5 scenario database (IPCC, 2018; Figure 1.29). The dominance of CO_2 compared to other well-mixed greenhouse gases (Figure 1.29; Chapter 5, Section 5.2.4) allows policymakers to make use of the carbon budget concept (Chapter 5, Section 5.5) in a policy context, in which GWP-weighted combinations of multiple greenhouse gases are used to define emission targets. A caveat is that cumulative GWP-weighted CO_2 equivalent emissions over the next decades do not yield exactly the same temperature outcomes as the same amount of cumulative CO_2 emissions, because atmospheric perturbation lifetimes of the various greenhouse gases differ. While carbon budgets are not derived using GWP-weighted emission baskets but rather by explicit modelling of non-CO_2 induced warming (Chapter 5, Section 5.5; Cross-Chapter Box 7.1 in Chapter 7), the policy frameworks based on GWP-weighted emission baskets can still make use of the insights from remaining cumulative carbon emissions for different warming levels.

The same cumulative CO_2 emissions could lead to a slightly different level of warming over time (Box 1.4). Rapid emissions followed by steep cuts and potentially net-negative emissions would be characterised by a higher maximum warming and faster warming rate, compared with the same cumulative CO_2 emissions spread over a longer period. As further explored in the WGIII assessment, one potential limitation when presenting emission pathway characteristics in cumulative emission budget categories is that path dependencies and lock-in effects (e.g. today's decisions regarding fossil fuel related infrastructure) play an important role in long-term mitigation strategies (Davis et al., 2010; Luderer et al., 2018). Similarly, high emissions early on might imply strongly net negative emissions (Minx et al., 2018) later on to reach the same cumulative emission and temperature target envelope by the end of the century (Box 1.4). This report explores options to address some of those potential issues from a WGI perspective (see Chapter 5, Sections

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.5.2 and 5.6.2).

[START FIGURE 1.29 HERE]

Figure 1.29: The role of CO_2 in driving future climate change in comparison to other greenhouse gases (GHGs). The GHGs included here are CH_4, N_2O, and 40 other long-lived, well-mixed GHGs. The blue shaded area indicates the approximate forcing exerted by CO_2 in Shared Socio-economic Pathways (SSP) scenarios, ranging from very low SSP1-1.9 to very high SSP5-8.5 (Chapter 7). The CO_2 concentrations under the SSP1-1.9 scenarios reach approximately 350 ppm after 2150, while those of SSP5-8.5 exceed 2000 ppm CO_2 in the longer term (through year 2300). Similarly to the dominant radiative forcing share at each point in time (lower area plots), cumulative GWP-100-weighted GHG emissions happen to be closely correlated with cumulative CO_2 emissions, allowing policymakers to make use of the carbon budget concept in a policy context with multi-gas GHG baskets as it exhibits relatively low variation across scenarios with similar cumulative emissions until 2050 (inset panel). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

[END FIGURE 1.29 HERE]

[START BOX 1.4 HERE]

Box 1.4: The relationships between 'net zero' emissions, temperature outcomes and carbon dioxide removal

Article 4 of the Paris Agreement sets an objective to 'achieve a balance between anthropogenic emissions by sources and removals by sinks of greenhouse gases' (Section 1.2). This box addresses the relationship between such a balance and the corresponding evolution of global surface temperature, with or without the deployment of large-scale Carbon Dioxide Removal (CDR), using the definitions of 'net zero CO_2 emissions' and 'net zero greenhouse gas (GHG) emissions' of the AR6 Glossary (Annex VII: Glossary).

'Net zero CO_2 emissions' is defined in AR6 as the condition in which anthropogenic CO_2 emissions are balanced by anthropogenic CO_2 removals over a specified period. Similarly, 'net zero GHG emissions' is the condition in which metric-weighted anthropogenic GHG emissions are balanced by metric-weighted anthropogenic GHG removals over a specified period. The quantification of net zero GHG emissions thus depends on the GHG emission metric chosen to compare emissions of different gases, as well as the time horizon chosen for that metric. (For a broader discussion of metrics, see Box 1.3 and Chapter 7, Section 7.6, and WGIII Cross-Chapter Box 2.)

Technical notes expanding on these definitions can be found as part of their respective entries in the Annex VII: Glossary. The notes clarify the relation between 'net zero' CO_2 and GHG emissions and the concept of carbon and GHG neutrality, and the metric usage set out in the Paris Rulebook (Decision 18/CMA.1, annex, paragraph 37).

A global net zero level of CO_2, or GHG, emissions will be achieved when the sum of anthropogenic emissions and removals across all countries, sectors, sources and sinks reaches zero. Achieving net zero CO_2 or GHG emissions globally, at a given time, does not imply that individual entities (i.e., countries, sectors) have to reach net zero emissions at that same point in time, or even at all (see WGIII, TS Box 4 and Chapter 3).

Net zero CO_2 and net zero GHG emissions differ in their implications for the subsequent evolution of global surface temperature. Net zero CO_2 emissions result in approximately stable CO_2-induced warming, but overall warming will depend on any further warming contribution of non-CO_2 GHGs. The effect of net zero GHG emissions on global surface temperature depends on the GHG emission metric chosen to aggregate emissions and removals of different gases. For GWP100 (the metric in which Parties to the Paris Agreement have decided to report their aggregated emissions and removals), net zero GHG emissions would generally imply a peak in global surface temperature, followed by a gradual decline (Chapter 7, Section 7.6.2; see also

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Chapter 4, Section 4.7.1 regarding the Zero Emission Commitment). However, other anthropogenic factors, such as aerosol emissions or land use-induced changes in albedo, may still affect the climate.

The definitions of net zero CO_2 and GHG should also be seen in relation to the various CDR methods discussed in the context of climate change mitigation (see Chapter 5, Section 5.6, which also includes an assessment of the response of natural sinks to CDR), and how it is employed in scenarios used throughout the WG I and III reports, as described in Section 1.6.1. (See also WGIII, Chapters 3, 7 and 12.)

For virtually all scenarios assessed by the IPCC, CDR is necessary to reach both global net zero CO_2 and net zero GHG emissions, to compensate for residual anthropogenic emissions. This is in part because for some sources of CO_2 and non-CO_2 emissions, abatement options to eliminate them have not yet been identified. For a given scenario, the choice of GHG metric determines how much net CDR is necessary to compensate for residual non-CO_2 emissions, in order to reach net zero GHG emissions (Chapter 7, Section 7.6.2).

If CDR is further used to go beyond net zero, to a situation with net-negative CO_2 emissions (i.e., where anthropogenic removals exceed anthropogenic emissions), anthropogenic CO_2-induced warming will decline. A further increase of CDR, until a situation with net zero or even net-negative GHG emissions is reached, would increase the pace at which historical human-induced warming is reversed after its peak (SR1.5, IPCC, 2018). Net-negative anthropogenic GHG emissions may become necessary to stabilize the global surface temperature in the long term, should climate feedbacks further affect natural GHG sinks and sources (see Chapter 5).

CDR can be achieved through a number of measures (Chapter 5, Section 5.6, and SRCCL). These include additional afforestation, reforestation, soil carbon management, biochar, direct air capture and carbon capture and storage (DACCS), and bioenergy with carbon capture and storage (BECCS) (de Coninck et al., 2018, SR1.5 Ch4; Minx et al., 2018; see also WGIII Chapters 7 and 12). Differences between Land Use, Land Use Change and Forestry (LULUCF) accounting rules, and scientific book-keeping approaches for CO_2 emissions and removals from the terrestrial biosphere, can result in significant differences between the amount of CDR that is reported in different studies (Grassi et al., 2017). Different measures to achieve CDR come with different risks, negative side effects and potential co-benefits – also in conjunction with sustainable development goals – that can inform choices around their implementation (Fuss et al., 2018; Roe et al., 2019, Chapter 5, Section 5.6). Technologies to achieve direct large-scale anthropogenic removals of non-CO_2 GHGs are speculative at present (Yoon et al., 2009; Ming et al., 2016; Kroeger et al., 2017; Jackson et al., 2019).

[END BOX 1.4 HERE]

1.7 Final remarks

The assessment in this Report is based on a rapidly growing body of new evidence from the peer-reviewed literature. Recently, scientific climate change research has doubled in output every 5–6 years; the majority of publications deal with issues related to the physical climate system (Burkett et al., 2014; Haunschild et al., 2016). The sheer volume of published, peer-reviewed literature on climate change presents a challenge to comprehensive, robust and transparent assessment.

The enhanced focus on regional climate in WGI AR6 further expands the volume of literature relative to AR5, including non-English language publications sometimes presented as reports (‘grey’ literature), particularly on topics such as regional observing networks and climate services. These factors enhance the challenge of discovering, accessing and assessing the relevant literature. The international, multi-lingual author teams of the IPCC AR6, combined with the open expert review process, help to minimise these concerns, but they remain a challenge.

Despite the key role of CMIP6 in this Report (Section 1.5), the number of studies evaluating its results and modelling systems remains relatively limited. At the time of publication, additional model results are still

ACCEPTED VERSION SUBJECT TO FINAL EDITS

becoming available. This reflects the need for close temporal alignment of the CMIP cycle with the IPCC assessment process, and the growing complexity of coordinated international modelling efforts.

Indigenous and local knowledge includes information about past and present climate states. However, assessing this knowledge, and integrating it with the scientific literature, remains a challenge to be met. This lack of assessment capability and integration leads to most WGI chapters still not including Indigenous and local knowledge in their assessment findings.

Spatial and temporal gaps in both historical and current observing networks, and the limited extent of paleoclimatic archives, have always posed a challenge for IPCC assessments. A relative paucity of long-term observations is particularly evident in Antarctica and in the depths of the ocean. Knowledge of previous cryospheric and oceanic processes is therefore incomplete. Sparse instrumental temperature observations prior to the industrial revolution makes it difficult to uniquely characterize a 'pre-industrial' baseline, although this report extends the assessment of anthropogenic temperature change further back in time than previous assessment cycles (Cross-Chapter Box 1.2, Chapter 7).

Common, integrating scenarios can never encompass all possible events that might induce radiative forcing in the future (Section 1.4). These may include large volcanic eruptions (see Cross-Chapter Box 4.1 in Chapter 4), the consequences of a major meteorite, smoke plumes following a conflict involving nuclear weapons, extensive geo-engineering, or a major pandemic (Cross-Chapter Box 1.6). Scenario-related research also often focuses on the 21st century. Post-2100 climate changes are not covered as comprehensively, and their assessment is limited. Those long-term climate changes, potentially induced by forcing over the 21st century (as in the case of sea level rise), are nevertheless relevant for decision making.

At the time of publication, the consequences of the COVID-19 pandemic on emissions, atmospheric abundances, radiative forcing and the climate (see Cross-Chapter Box 6.1 in Chapter 6), and on observations (Section 1.5.1), are not yet fully evident. Their assessment in this report is thus limited.

Frequently Asked Questions

FAQ 1.1: Do we understand climate change better now compared to when the IPCC started?

Yes, much better. The first IPCC report, released in 1990, concluded that human-caused climate change would soon become evident, but could not yet confirm that it was already happening. Today, evidence is overwhelming that the climate has indeed changed since the pre-industrial era and that human activities are the principal cause of that change. With much more data and better models, we also understand more about how the atmosphere interacts with the ocean, ice, snow, ecosystems and land surfaces of the Earth. Computer climate simulations have also improved dramatically, incorporating many more natural processes and providing projections at much higher resolutions.

Since the first IPCC report in 1990, large numbers of new instruments have been deployed to collect data in the air, on land, at sea and from outer space. These instruments measure temperature, clouds, winds, ice, snow, ocean currents, sea level, soot and dust in the air, and many other aspects of the climate system. New satellite instruments have also provided a wealth of increasingly fine-grained data. Additional data from older observing systems and even hand-written historical records are still being incorporated into observational datasets, and these datasets are now better integrated and adjusted for historical changes in instruments and measurement techniques. Ice cores, sediments, fossils, and other new evidence from the distant past have taught us much about how Earth's climate has changed throughout its history.

Understanding of climate system processes has also improved. For example, in 1990 very little was known about how the deep ocean responds to climate change. Today, reconstructions of deep ocean temperatures extend as far back as 1871. We now know that the oceans absorb most of the excess energy trapped by greenhouse gases and that even the deep ocean is warming up. As another example, in 1990, relatively little was known about exactly how or when the gigantic ice sheets of Greenland and Antarctica would respond to warming. Today, much more data and better models of ice sheet behaviour reveal unexpectedly high melt rates that will lead to major changes within this century, including substantial sea level rise (see FAQ 9.2).

The major natural factors contributing to climate change on time scales of decades to centuries are volcanic eruptions and variations in the sun's energy output. Today, data show that changes in incoming solar energy since 1900 have contributed only slightly to global warming, and they exhibit a slight downward trend since the 1970s. Data also show that major volcanic eruptions have sometimes cooled the entire planet for relatively short periods of time (typically several years) by erupting aerosols (tiny airborne particles) high into the atmosphere.

The main human causes of climate change are the heat-absorbing greenhouse gases released by fossil fuel combustion, deforestation, and agriculture, which warm the planet, and aerosols such as sulphate from burning coal, which have a short-term cooling effect that partially counteracts human-caused warming. Since 1990, we have more and better observations of these human factors as well as improved historical records, resulting in more precise estimates of human influences on the climate system (see FAQ 3.1).

While most climate models in 1990 focused on the atmosphere, using highly simplified representations of oceans and land surfaces, today's Earth system simulations include detailed models of oceans, ice, snow, vegetation and many other variables. An important test of models is their ability to simulate Earth's climate over the period of instrumental records (since about 1850). Several rounds of such testing have taken place since 1990, and the testing itself has become much more rigorous and extensive. As a group and at large scales, models have predicted the observed changes well in these tests (see FAQ 3.3). Since there is no way to do a controlled laboratory experiment on the actual Earth, climate model simulations can also provide a kind of 'alternate Earth' to test what would have happened without human influences. Such experiments show that the observed warming would not have occurred without human influence. .

Finally, physical theory predicts that human influences on the climate system should produce specific patterns of change, and we see those patterns in both observations and climate simulations. For example, nights are warming faster than days, less heat is escaping to space, and the lower atmosphere (troposphere) is warming but the upper atmosphere (stratosphere) has cooled. These confirmed predictions are all evidence of

ACCEPTED VERSION SUBJECT TO FINAL EDITS

changes driven primarily by increases in greenhouse gas concentrations rather than natural causes.

[START FAQ 1.1, FIGURE 1 HERE]

FAQ 1.1, Figure 1: Sample elements of climate understanding, observations and models as assessed in the IPCC First Assessment Report (1990) and Sixth Assessment Report (2021). Many other advances since 1990, such as key aspects of theoretical understanding, geological records and attribution of change to human influence, are not included in this figure because they are not readily represented in this simple format. Fuller explications of the history of climate knowledge are available in the introductory chapters of the IPCC Fourth and Sixth Assessment Reports.

[END FAQ 1.1, FIGURE 1 HERE]

FAQ 1.2: Where is climate change most apparent?

The signs of climate change are unequivocal at the global scale and are increasingly apparent on smaller spatial scales. The high northern latitudes show the largest temperature increase with clear effects on sea ice and glaciers. The warming in the tropical regions is also apparent because the natural year-to-year variations in temperature there are small. Long-term changes in other variables such as rainfall and some weather and climate extremes have also now become apparent in many regions.

It was first noticed that the planet's land areas were warming in the 1930s. Although increasing atmospheric carbon dioxide concentrations were suggested as part of the explanation, it was not certain at the time whether the observed warming was part of a long-term trend or a natural fluctuation – global warming had not yet become apparent. But the planet continued to warm, and by the 1980s the changes in temperature had become obvious or, in other words, the signal had *emerged*.

Imagine you had been monitoring temperatures at the same location for the past 150 years. What would you have experienced? When would the warming have become noticeable in your data? The answers to these questions depend on where on the planet you are.

Observations and climate model simulations both demonstrate that the largest long-term warming trends are in the high northern latitudes and the smallest warming trends over land are in tropical regions. However, the year-to-year variations in temperature are smallest in the tropics, meaning that the changes there are also apparent, relative to the range of past experiences (see FAQ 1.2, Figure 1).

Changes in temperature also tend to be more apparent over land areas than over the open ocean and are often most apparent in regions which are more vulnerable to climate change. It is expected that future changes will continue to show the largest signals at high northern latitudes, but with the most apparent warming in the tropics. The tropics also stand to benefit the most from climate change mitigation in this context, as limiting global warming will also limit how far the climate shifts relative to past experience.

Changes in other climate variables have also become apparent at smaller spatial scales. For example, changes in average rainfall are becoming clear in some regions, but not in others, mainly because natural year-to-year variations in precipitation tend to be large relative to the magnitude of the long-term trends. However, extreme rainfall is becoming more intense in many regions, potentially increasing the impacts from inland flooding (see FAQ 8.2). Sea levels are also clearly rising on many coastlines, increasing the impacts of inundation from coastal storm surges, even without any increase in the number of storms reaching land. A decline in the amount of Arctic sea ice is apparent, both in the area covered and in its thickness, with implications for polar ecosystems.

When considering climate-related impacts, it is not necessarily the size of the change which is most important. Instead, it can be the rate of change or it can also be the size of the change relative to the natural variations of the climate to which ecosystems and society are adapted. As the climate is pushed further away

ACCEPTED VERSION SUBJECT TO FINAL EDITS

from past experiences and enters an unprecedented state, the impacts can become larger, along with the challenge of adapting to them.

How and when a long-term trend becomes distinguishable from shorter-term natural variations depends on the aspect of climate being considered (e.g., temperature, rainfall, sea ice or sea level), the region being considered, the rate of change, and the magnitude and timing of natural variations. When assessing the local impacts from climate change, both the size of the change and the amplitude of natural variations matter.

[START FAQ 1.2, FIGURE 1 HERE]

FAQ 1.2, Figure 1: **Observed variations in regional temperatures since 1850** (data from Berkeley Earth). Regions in high latitudes, such as mid-North America (40ºN–64ºN, 140ºW–60ºW, left), have warmed by a larger amount than regions at lower latitudes, such as Tropical South America (10ºS–10ºN, 84ºW–16ºW, right), but the natural variations are also much larger at high latitudes (darker and lighter shading represents 1 and 2 standard deviations, respectively, of natural year-to-year variations). The signal of observed temperature change emerged earlier in Tropical South America than mid-North America even though the changes were of a smaller magnitude. (Note that those regions were chosen because of the longer length of their observational record, see Figure 1.14 for more regions).

[END FAQ 1.2, FIGURE 1 HERE]

FAQ 1.3: What can past climate teach us about the future?

In the past, the Earth has experienced prolonged periods of elevated greenhouse gas concentrations that caused global temperatures and sea levels to rise. Studying these past warm periods informs us about the potential long-term consequences of increasing greenhouse gases in the atmosphere.

Rising greenhouse gas concentrations are driving profound changes to the Earth system, including global warming, sea level rise, increases in climate and weather extremes, ocean acidification, and ecological shifts (see FAQ 2.2, FAQ 7.1). The vast majority of instrumental observations of climate began during the 20th century, when greenhouse gas emissions from human activities became the dominant driver of changes in Earth's climate (see FAQ 3.1).

As scientists seek to refine our understanding of Earth's climate system and how it may evolve in coming decades to centuries, past climate states provide a wealth of insights. Data about these past states help to establish the relationship between natural climate drivers and the history of changes in global temperature, global sea levels, the carbon cycle, ocean circulation, and regional climate patterns, including climate extremes. Guided by such data, scientists use Earth system models to identify the chain of events underlying the transitions between past climatic states (see FAQ 3.3). This is important because during present-day climate change, just as in past climate changes, some aspects of the Earth system (e.g., surface temperature) respond to changes in greenhouse gases on a time scale of decades to centuries, while others (e.g., sea level and the carbon cycle) respond over centuries to millennia (see FAQ 5.3). In this way, past climate states serve as critical benchmarks for climate model simulations, improving our understanding of the sequences, rates, and magnitude of future climate change over the next decades to millennia.

Analyzing previous warm periods caused by natural factors can help us understand how key aspects of the climate system evolve in response to warming. For example, one previous warm-climate state occurred roughly 125,000 years ago, during the Last Interglacial period, when slight variations in the Earth's orbit triggered a sequence of changes that caused about 1°C–2°C of global warming and about 2–8 m of sea level rise relative to the 1850-1900, even though atmospheric carbon dioxide concentrations were similar to 1850-1900 values (FAQ 1.3, Figure 1). Modelling studies highlight that increased summer heating in the higher latitudes of the Northern Hemisphere during this time caused widespread melting of snow and ice, reducing the reflectivity of the planet and increasing the absorption of solar energy by the Earth's surface. This gave rise to global-scale warming, which led in turn to further ice loss and sea level rise. These self-reinforcing positive *feedback cycles* are a pervasive feature of Earth's climate system, with clear implications for future

ACCEPTED VERSION SUBJECT TO FINAL EDITS

climate change under continued greenhouse gas emissions. In the case of sea level rise, these cycles evolved over several centuries to millennia, reminding us that the rates and magnitude of sea level rise in the 21st century are just a fraction of the sea level rise that will ultimately occur after the Earth system fully adjusts to current levels of global warming.

Roughly 3 million years ago, during the Pliocene Epoch, the Earth witnessed a prolonged period of elevated temperatures (2.5°C–4°C higher than 1850-1900) and higher sea levels (5–25 m higher than 1850-1900), in combination with atmospheric carbon dioxide concentrations similar to present-day. The fact that Pliocene atmospheric carbon dioxide concentrations were similar to present, while global temperatures and sea levels were significantly higher, reflects the difference between an Earth system that has fully-adjusted to changes in natural drivers (the Pliocene) and one where greenhouse gases concentrations, temperature, and sea level rise are still increasing (present-day). Much about the transition into the Pliocene climate state – in terms of key causes, the role of cycles that hastened or slowed the transition, and the rate of change in climate indicators such as sea level – remain topics of intense study by climate researchers using a combination of paleoclimate observations and Earth system models. Insights from such studies may help to reduce the large uncertainties around estimates of global sea level rise by 2300, which range from 0.3 m to 3 m above 1850-1900 (in a low-emissions scenario) to as much as 16 m higher than 1850-1900 (in a very high-emissions scenario that includes accelerating structural disintegration of the polar ice sheets).

While present-day warming is unusual in the context of the recent geologic past in several different ways (see FAQ 2.1), past warm climate states present a stark reminder that the long-term adjustment to present-day atmospheric carbon dioxide concentrations has only just begun. That adjustment will continue over the coming centuries to millennia.

[START FAQ 1.3, FIGURE 1 HERE]

FAQ 1.3, Figure 1: Comparison of past, present and future. Schematic of atmospheric carbon dioxide concentrations, global temperature, and global sea level during previous warm periods as compared to 1850-1900, present-day (2011-2020), and future (2100) climate change scenarios corresponding to low-emissions scenarios (SSP1-2.6; lighter colour bars) and very high emissions scenarios (SSP5-8.5; darker colour bars).

Appendix 1.A

[START TABLE 1.A.1 HERE]

Table 1.A.1: Historical overview of major conclusions of IPCC assessment reports. The table repeats Table 1.1 from the IPCC Fifth Assessment Report (AR5; Cubasch et al., 2013) and extends it with the AR5 and AR6 key findings. The table provides a non-comprehensive selection of key Summary for Policymakers (SPM) statements from previous assessment reports—IPCC First Assessment Report (FAR; IPCC, 1990b), IPCC Second Assessment Report (SAR; IPCC, 1995b), IPCC Third Assessment Report (TAR; IPCC, 2001b), IPCC Fourth Assessment Report (AR4; IPCC, 2007b) , IPCC Fifth Assessment Report (AR5; IPCC, 2013b), and the IPCC Sixth Assessment Report (AR6; IPCC, 2021) —with a focus on global mean surface air temperature and sea level change as two policy relevant quantities that have been covered in IPCC since the FAR.

[Placeholder: the column for AR6 will be filled out once the SPM is drafted, and this column will be finalized once the final version of the AR6 SPM is approved]

Topic	FAR SPM Statement (1990)	SAR SPM Statement (1995)	TAR SPM Statement (2001)	AR4 SPM Statement (2007)	AR5 SPM statement (2013)	AR6 SPM statement (2021)
Human and Natural Drivers of Climate Change	There is a natural greenhouse effect, which already keeps the Earth warmer than it would otherwise be. Emissions resulting from human activities are substantially increasing the atmospheric concentrations of the greenhouse gases carbon dioxide, methane, chlorofluorocarbons and nitrous oxide. These increases will enhance the greenhouse effect, resulting on average in an additional warming of the Earth's surface.	Greenhouse gas concentrations have continued to increase. These trends can be attributed largely to human activities, mostly fossil fuel use, land use change and agriculture.	Emissions of greenhouse gases and aerosols due to human activities continue to alter the atmosphere in ways that are expected to affect the climate. The atmospheric concentration of CO_2 has increased by 31% since 1750 and that of methane by 151%.	Global atmospheric concentrations of carbon dioxide, methane and nitrous oxide have increased markedly as a result of human activities since 1750 and now far exceed pre-industrial values determined from ice cores spanning many thousands of years. The global increases in carbon dioxide concentration are due primarily to fossil fuel use and land use change, while those of	Total radiative forcing is positive, and has led to an uptake of energy by the climate system. The largest contribution to total radiative forcing is caused by the increase in the atmospheric concentration of CO_2 since 1750.	

ACCEPTED VERSION SUBJECT TO FINAL EDITS

				methane and nitrous oxide are primarily due to agriculture.		
	Continued emissions of these gases at present rates would commit us to increased concentrations for centuries ahead.	Anthropogenic aerosols are short-lived and tend to produce negative radiative forcing.	Anthropogenic aerosols are short-lived and mostly produce negative radiative forcing by their direct effect. There is more evidence for their indirect effect, which is negative, although of very uncertain magnitude.	*Very high confidence* that the global average net effect of human activities since 1750 has been one of warming, with a radiative forcing of +1.6 [+0.6 to +2.4] W m^{-2}.	The total anthropogenic radiative forcing (RF) for 2011 relative to 1750 is 2.29 [1.13 to 3.33] W m^{-2}), and it has increased more rapidly since 1970 than during prior decades. The total anthropogenic RF best estimate for 2011 is 43% higher than that reported in AR4 for the year 2005.	
			Natural factors have made small contributions to radiative forcing over the past century.		The total natural RF from solar irradiance changes and stratospheric volcanic aerosols made only a small contribution to the net radiative forcing throughout the last century, except for brief periods after large volcanic eruptions.	
Observations of Recent Climate Change - Temperature	Global mean surface air temperature has increased by 0.3°C to 0.6°C over the last 100 years, with the five global-average	Climate has changed over the past century. Pinatubo volcanic eruption.	climate system.	increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level.	unprecedented over decades to millennia. The atmosphere and ocean have warmed, the amounts of snow and ice have diminished, sea level has risen, and the concentrations of greenhouse gases have increased.	
			The global average temperature has increased since 1861. Over the 20th century the increase has been 0.6°C.	Eleven of the last twelve years (1995–2006) rank among the 12 warmest years in the instrumental record of global surface temperature (since 1850). The updated 100-year linear trend (1906 to 2005) of 0.74°C [0.56°C to 0.92°C] is therefore larger than the corresponding trend for 1901 to 2000 given in the TAR of 0.6°C [0.4°C to 0.8°C].	Each of the last three decades has been successively warmer at the Earth's surface than any preceding decade since 1850. The globally averaged combined land and ocean surface temperature data as calculated by a linear trend, show a warming of 0.85 [0.65 to 1.06] °C, over the period 1880 to 2012.	
			Some important aspects of climate appear not to have changed.	Some aspects of climate have not been observed to change.		
Observations of Recent Climate Change - Sea	Over the same period global sea level has increased by 10 to 20 cm. These increases have not	Global sea level has risen by between 10 and 25 cm over the past 100 years and	Tide gauge data show that global average sea level rose between 0.1 and 0.2 m during the	Global average sea level rose at an average rate of 1.8 [1.3 to 2.3] mm yr^{-1} over	The rate of sea level rise since the mid-19th century has been larger than the mean rate	

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Level	been smooth with time nor uniform over the globe.	much of the rise may be related to the increase in global mean temperature.	20th century.	1961 to 2003. The rate was faster over 1993 to 2003: about 3.1 [2.4 to 3.8] mm yr^{-1}. The total 20th century rise is estimated to be 0.17 [0.12 to 0.22] m.	during the previous two millennia (*high confidence*). Over the period 1901 to 2010, global mean sea level rose by 0.19 [0.17 to 0.21] m.	
Observations of Recent Climate Change - Ocean Heat Content			Global ocean heat content has increased since the late1950s, the period for which adequate observations of sub-surface ocean temperatures have been available.	Observations since 1961 show that the average temperature of the global ocean has increased to depths of at least 3000 m and that the ocean has been absorbing more than 80% of the heat added to the climate system. Such warming causes seawater to expand, contributing to sea level rise.	Ocean warming dominates the increase in energy stored in the climate system, accounting for more than 90% of the energy accumulated between 1971 and 2010 (*high confidence*). It is *virtually certain* that the upper ocean (0−700 m) warmed from 1971 to 2010, and it *likely* warmed between the 1870s and 1971. On a global scale, the ocean warming is largest near the surface, and the upper 75 m warmed by 0.11 [0.09 to 0.13] °C per decade over the period 1971 to 2010. Instrumental biases in upper-ocean temperature records have been identified	

ACCEPTED VERSION SUBJECT TO FINAL EDITS

					and reduced, enhancing confidence in the assessment of change.	
Observations of Recent Climate Change - Carbon Cycle / Ocean Acidification				Increasing atmospheric carbon dioxide concentrations lead to increasing acidification of the ocean. Projections based on SRES scenarios give reductions in average global surface ocean pH of between 0.14 and 0.35 units over the 21st century, adding to the present decrease of 0.1 units since pre-industrial times.	The atmospheric concentrations of carbon dioxide, methane, and nitrous oxide have increased to levels unprecedented in at least the last 800,000 years. Carbon dioxide concentrations have increased by 40% since pre-industrial times, primarily from fossil fuel emissions and secondarily from net land use change emissions. The ocean has absorbed about 30% of the emitted anthropogenic carbon dioxide, causing ocean acidification.	
A Palaeoclimatic Perspective	Climate varies naturally on all timescales from hundreds of millions of years down to the year-to-year. Prominent in the Earth's history have been the 100,000-year glacial–interglacial cycles when climate was mostly cooler	The limited available evidence from proxy climate indicators suggests that the 20th century global mean temperature is at least as warm as any other century since at least 1400 AD. Data prior to	New analyses of proxy data for the Northern Hemisphere indicate that the increase in temperature in the 20th century is *likely* to have been the largest of any century during the past 1,000 years. It is also	Palaeoclimatic information supports the interpretation that the warmth of the last half-century is unusual in at least the previous 1,300 years.	In the Northern Hemisphere, 1983–2012 was *likely* the warmest 30-year period of the last 1400 years (*medium confidence*).	
				The last time the polar regions were	There is *very high confidence* that	

ACCEPTED VERSION SUBJECT TO FINAL EDITS

	than at present. Global surface temperatures have typically varied by 5°C to 7°C through these cycles, with large changes in ice volume and sea level, and temperature changes as great as 10°C to 15°C in some middle and high latitude regions of the Northern Hemisphere. Since the end of the last ice age, about 10,000 years ago, global surface temperatures have probably fluctuated by little more than 1°C. Some fluctuations have lasted several centuries, including the period 1400-1900 which ended in the 19th century and which appears to have been global in extent.	1400 are too sparse to allow the reliable estimation of global mean temperature.	*likely* that, in the Northern Hemisphere, the 1990s was the warmest decade and 1998 the warmest year. Because less data are available, less is known about annual averages prior to 1,000 years before present and for conditions prevailing in most of the Southern Hemisphere prior to 1861.	significantly warmer than present for an extended period (about 125,000 years ago), reductions in polar ice volume led to 4 to 6 m of sea level rise.	maximum global mean sea level during the last interglacial period (129,000 to 116,000 years ago) was, for several thousand years, at least 5 m higher than present, and *high confidence* that it did not exceed 10 m above present.	
Understanding and Attributing Climate Change	The size of this warming is broadly consistent with predictions of climate models, but it is also of the same magnitude as natural climate variability. Thus, the observed increase could be largely due to this natural variability; alternatively, this variability and other	The balance of evidence suggests a discernible human influence on global climate. Simulations with coupled atmosphere–ocean models have provided important information about decade to century timescale	There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities. There is a longer and more scrutinized temperature record and new model estimates of variability.	Most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations. Discernible human	Human influence on the climate system is clear. It is *extremely likely* that more than half of the observed increase in global average surface temperature from 1951 to 2010 was caused by the anthropogenic increase in greenhouse	

ACCEPTED VERSION SUBJECT TO FINAL EDITS

	human factors could have offset a still larger human-induced greenhouse warming. The unequivocal detection of the enhanced greenhouse effect from observations is *not likely* for a decade or more.	natural internal climate variability.	Reconstructions of climate data for the past 1,000 years indicate this warming was unusual and is *unlikely* to be entirely natural in origin.	influences now extend to other aspects of climate, including ocean warming, continental-average temperatures, temperature extremes and wind patterns.	gas concentrations and other anthropogenic forcings together. The best estimate of the human-induced contribution to warming is similar to the observed warming over this period.	
Projections of Future Changes in Climate - Temperature	Under the IPCC Business-as-Usual emissions of greenhouse gases, a rate of increase of global mean temperature during the next century of about 0.3°C per decade (with an uncertainty range of 0.2°C to 0.5°C per decade); this is greater than that seen over the past 10,000 years.	Climate is expected to continue to change in the future. For the mid-range IPCC emission scenario, IS92a, assuming the 'best estimate' value of climate sensitivity and including the effects of future increases in aerosols, models project an increase in global mean surface air temperature relative to 1990 of about 2°C by 2100.	Global average temperature and sea level are projected to rise under all IPCC SRES scenarios. The globally averaged surface temperature is projected to increase by 1.4°C to 5.8°C over the period 1990 to 2100.	For the next two decades, a warming of about 0.2°C per decade is projected for a range of SRES emission scenarios. Even if the concentrations of all greenhouse gases and aerosols had been kept constant at year 2000 levels, a further warming of about 0.1°C per decade would be expected.	Global surface temperature change for the end of the 21st century is *likely* to exceed 1.5°C relative to 1850 to 1900 for all RCP scenarios except RCP2.6. It is likely to exceed 2°C for RCP6.0 and RCP8.5, and *more likely than not* to exceed 2°C for RCP4.5. Warming will continue beyond 2100 under all RCP scenarios except RCP2.6. Warming will continue to exhibit interannual-to-decadal variability and will not be regionally uniform.	
			Confidence in the ability of models to project future climate has increased.	There is now higher confidence in projected patterns of warming and other regional-scale features,	Climate models have improved since the AR4. Models reproduce observed continental-scale	

ACCEPTED VERSION SUBJECT TO FINAL EDITS

				including changes in wind patterns, precipitation and some aspects of extremes and of ice.	surface temperature patterns and trends over many decades, including the more rapid warming since the mid-20th century and the cooling immediately following large volcanic eruptions.	
			Anthropogenic climate change will persist for many centuries.	Anthropogenic warming and sea level rise would continue for centuries, even if greenhouse gas concentrations were to be stabilised.	Cumulative emissions of CO_2 largely determine global mean surface warming by the late 21st century and beyond. Most aspects of climate change will persist for many centuries even if emissions of CO_2 are stopped. This represents a substantial multi-century climate change commitment created by past, present and future emissions of CO_2.	
Projections of Future Changes in Climate - Sea Level	An average rate of global mean sea level rise of about 6 cm per decade over the next century (with an uncertainty range of 3 to 10 cm per decade) is projected.	For the IS92a scenario, assuming the 'best estimate' values of climate sensitivity and of ice melt sensitivity to warming and including the effects of future	Global mean sea level is projected to rise by 0.09 to 0.88 m between 1990 and 2100.	Global sea level rise for the range of scenarios is projected as 0.18 to 0.59 m by the end of the 21st century.	Global mean sea level rise for 2081–2100 relative to 1986–2005 will *likely* be in the ranges of 0.26 to 0.55 m for RCP2.6, 0.32 to 0.63 m for RCP4.5, 0.33 to 0.63 m for	

ACCEPTED VERSION SUBJECT TO FINAL EDITS

		changes in aerosol concentrations, models project a sea level rise of about 50 cm from the present to 2100. The corresponding 'low' and 'high' projections are 15 and 95 cm.			RCP6.0, and 0.45 to 0.82 m for RCP8.5.	
Projections of Future Changes in Climate - AMOC		Most simulations show a reduction in the strength of the North Atlantic thermohaline circulation. Future unexpected, large and rapid climate system changes are difficult to predict. These arise from the non-linear nature of the climate system. Examples include rapid circulation changes in the North Atlantic.	Most models show weakening of the ocean thermohaline circulation, which leads to a reduction of the heat transport into high latitudes of the Northern Hemisphere. However, even in models where the thermohaline circulation weakens, there is still a warming over Europe due to increased greenhouse gases. The current projections using climate models do not exhibit a complete shut-down of the thermohaline circulation by 2100. Beyond 2100, the thermohaline circulation could completely, and possibly irreversibly, shut-down in either hemisphere if	Based on current model simulations, it is *very likely* that the meridional overturning circulation (MOC) of the Atlantic Ocean will slow down during the 21st century. It is *very unlikely* that the MOC will undergo a large abrupt transition during the 21st century. Longer-term changes in the MOC cannot be assessed with confidence.	It is *very likely* that the Atlantic Meridional Overturning Circulation (AMOC) will weaken over the 21st century. It is *very unlikely* that the AMOC will undergo an abrupt transition or collapse in the 21st century for the scenarios considered. There is *low confidence* in assessing the evolution of the AMOC beyond the 21st century because of the limited number of analyses and equivocal results. However, a collapse beyond the 21st century for large sustained warming cannot be excluded.

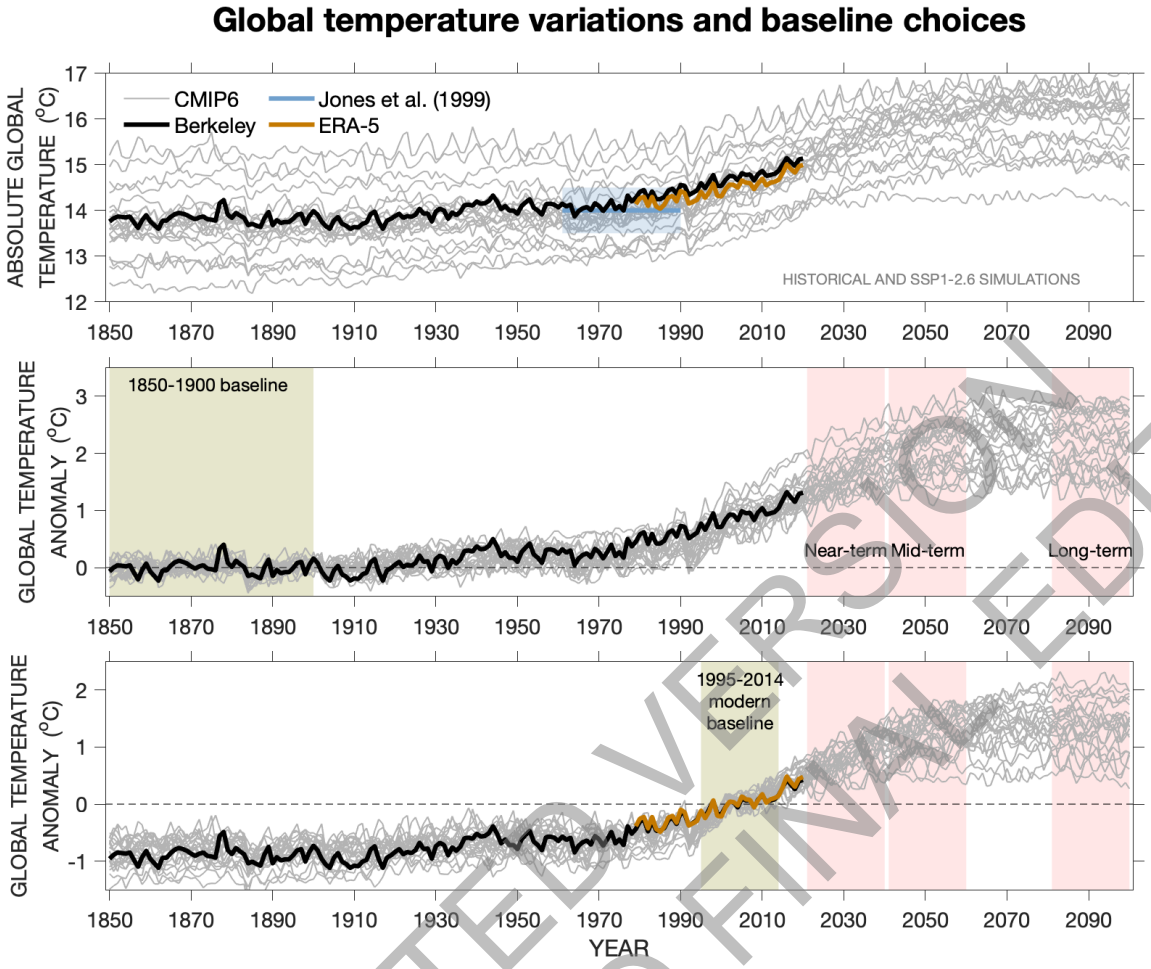

Figure 1.11: Choice of baseline matters when comparing observations and model simulations. Global mean surface air temperature (GSAT, grey) from a range of CMIP6 historical simulations (1850–2014, 25 models) and SSP1-2.6 (2015–2100) using absolute values (top) and anomalies relative to two different baselines: 1850–1900 (middle) and 1995–2014 (bottom). An estimate of GSAT from a reanalysis (ERA-5, orange, 1979–2020) and an observation-based estimate of global mean surface air temperature (GMST) (Berkeley Earth, black, 1850–2020) are shown, along with the mean GSAT for 1961–1990 estimated by Jones et al. (1999), light blue shading, 14.0±0.5°C). Using the more recent baseline (bottom) allows the inclusion of datasets which do not include the periods of older baselines. The middle and bottom panels have scales which are the same size but offset. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

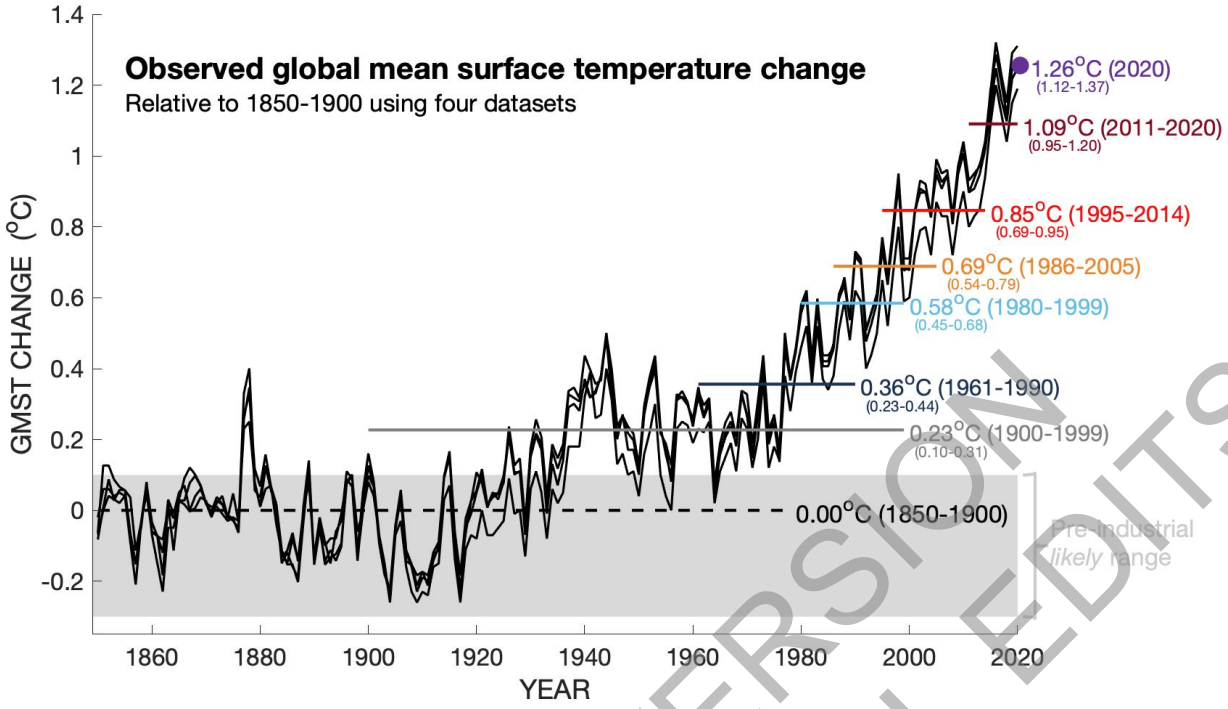
ACCEPTED VERSION SUBJECT TO FINAL EDITS



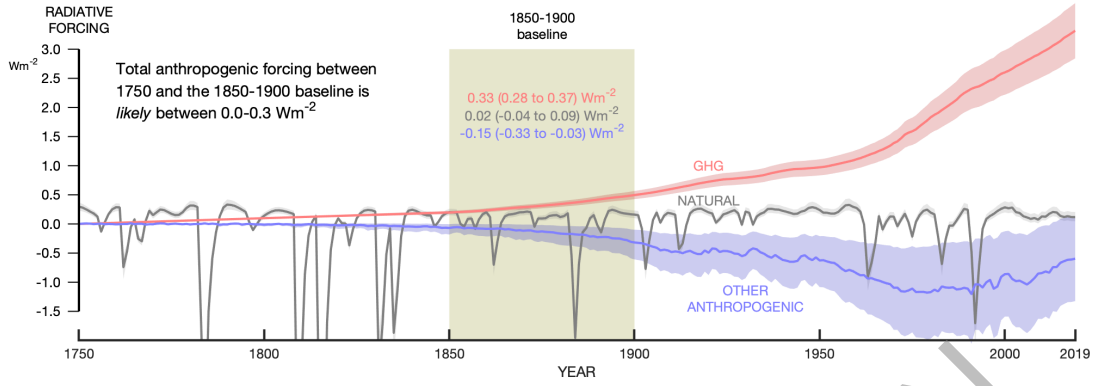


Figure 1.12: Global warming over the instrumental period. Observed global mean surface temperature (GMST) from four datasets, relative to the average temperature of 1850–1900 in each dataset (see Cross-Chapter Box 2.3 and Section 2.3.1.1 for more details). The shaded grey band indicates the assessed *likely* range for the period around 1750 (see Cross-Chapter Box 1.2). Different reference periods are indicated by the coloured horizontal lines, and an estimate of total GMST change up to that period is given, enabling a translation of the level of warming between different reference periods. The reference periods are all chosen because they have been used in the AR6 or previous IPCC assessment reports. The value for the 1981–2010 reference period, used as a 'climate normal' period by the World Meteorological Organization, is the same as the 1986–2005 reference period shown. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

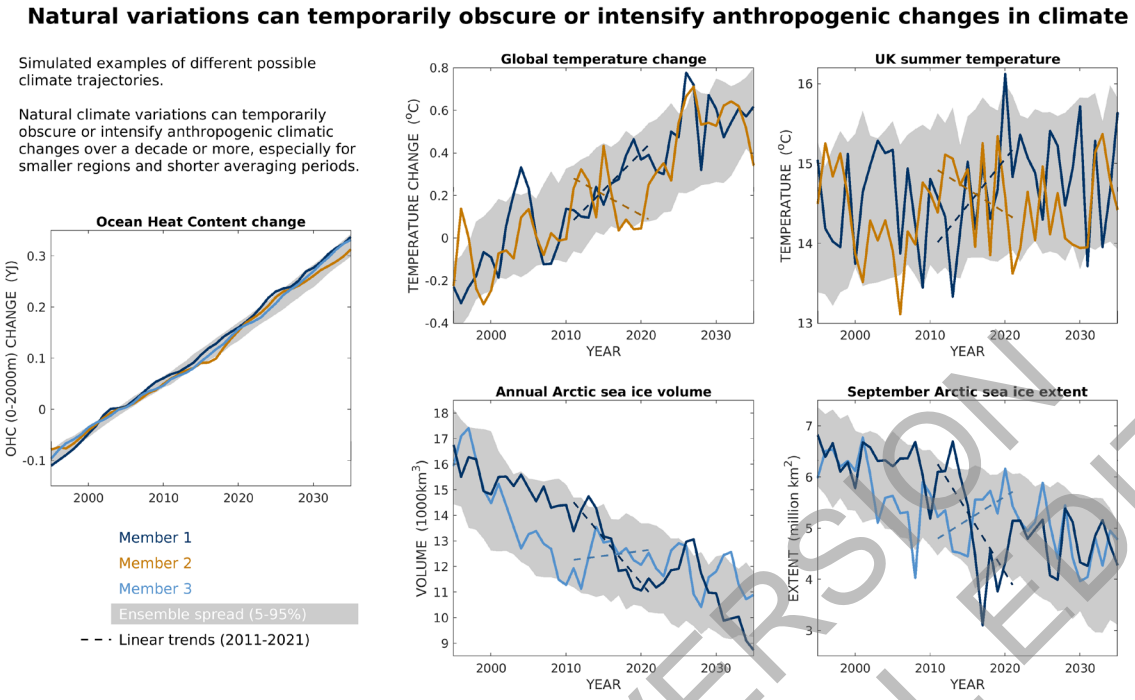
ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Chapter Box 1.2, Figure 1: Changes in radiative forcing from 1750 to 2019. The radiative forcing estimates from the AR6 emulator (see Cross-Chapter Box 7.1 in Chapter 7) are split into GHG, other anthropogenic (mainly aerosols and land use) and natural forcings, with the average over the 1850–1900 baseline shown for each. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS



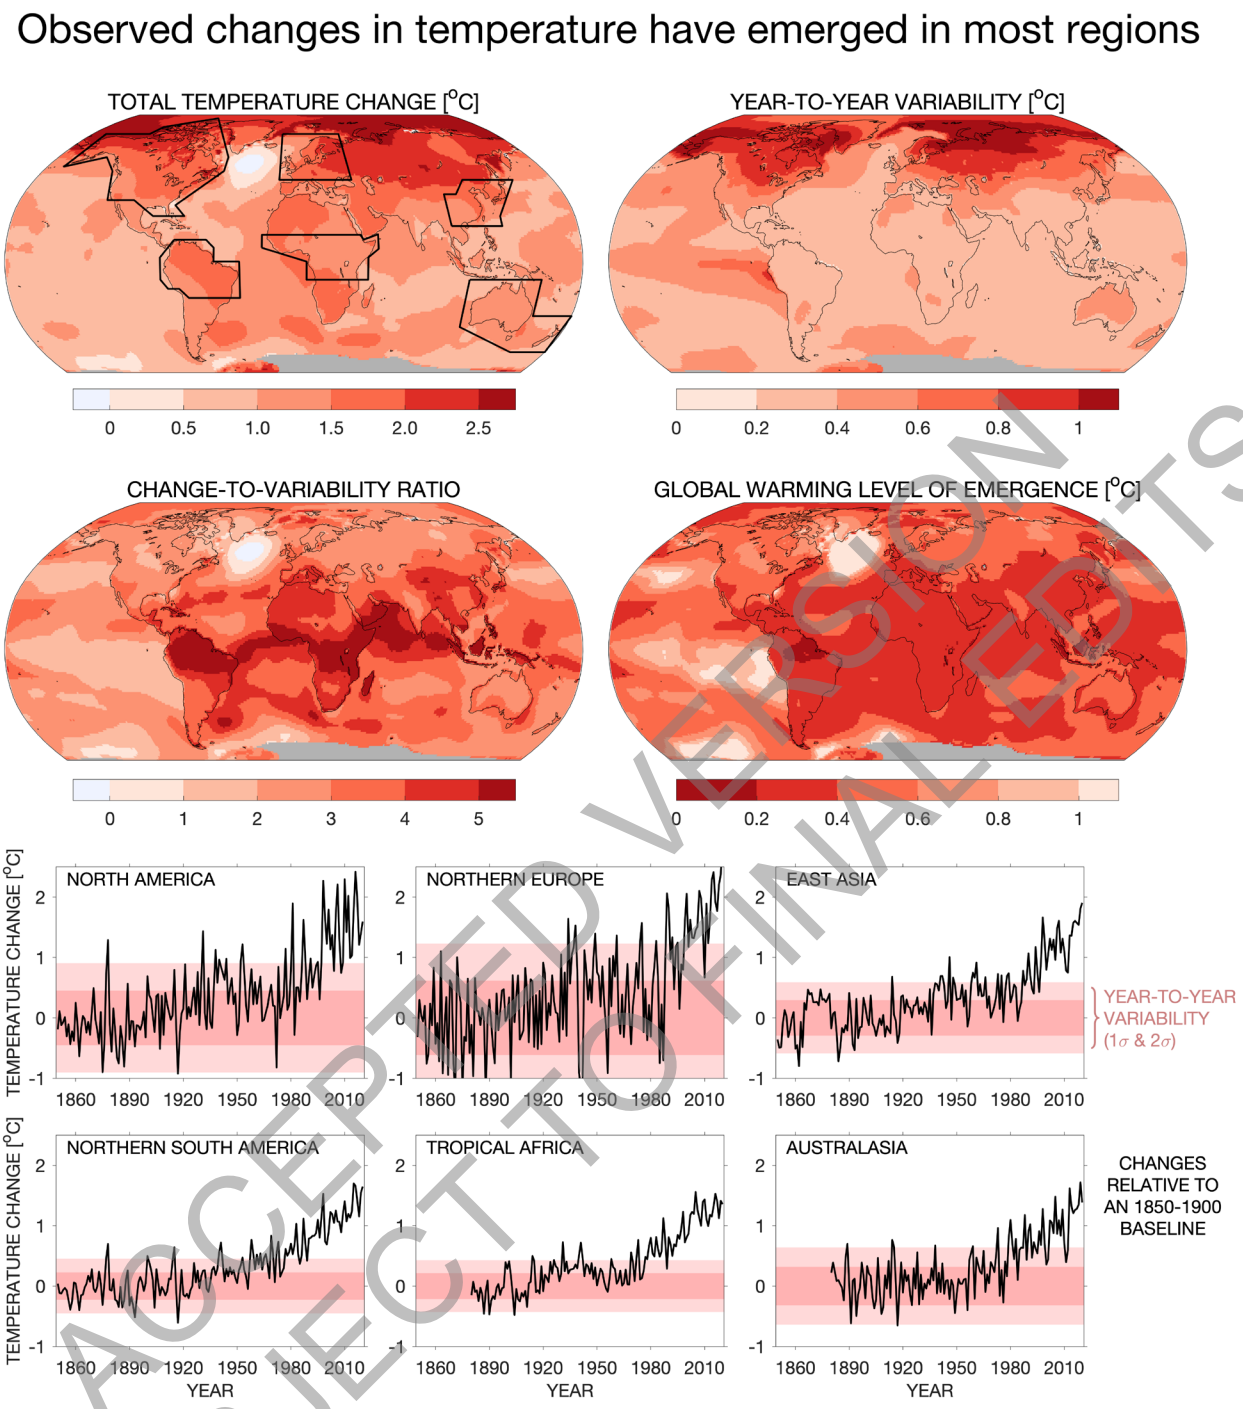


Figure 1.13: Simulated changes in various climate indicators under historical and RCP4.5 scenarios using the MPI ESM Grand Ensemble. The grey shading shows the 5–95% range from the 100-member ensemble. The coloured lines represent individual example ensemble members, with linear trends for the 2011–2021 period indicated by the thin dashed lines. Changes in Ocean Heat Content (OHC) over the top 2000m represents the integrated signal of global warming (left). The top row shows surface air temperature-related indicators (annual GSAT change and UK summer temperatures) and the bottom row shows Arctic sea-ice related indicators (annual ice volume and September sea ice extent). For smaller regions and for shorter time period averages the variability increases and simulated short-term trends can temporarily obscure or intensify anthropogenic changes in climate. Data from Maher et al., (2019). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Figure 1.14: The observed emergence of changes in temperature. Top left: the total change in temperature estimated for 2020 relative to 1850–1900 (following Hawkins et al. 2020), showing the largest warming in the Arctic. Top right: the amplitude of estimated year-to-year variations in temperature. Middle left: the ratio of the observed total change in temperature and the amplitude of temperature variability (the 'signal-to-noise (S/N) ratio'), showing that the warming is most apparent in the tropical regions (also see FAQ1.2). Middle right: the global warming level at which the change in local temperature becomes larger than the local year-to-year variability. The bottom panels show time series of observed annual mean surface air temperatures over land in various example regions, as indicated as boxes in the top left panel. The 1 and 2 standard deviations of estimated year-to-year variations for that region are shown by the pink shaded bands. Observed temperature data from Berkeley Earth (Rohde and Hausfather, 2020). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

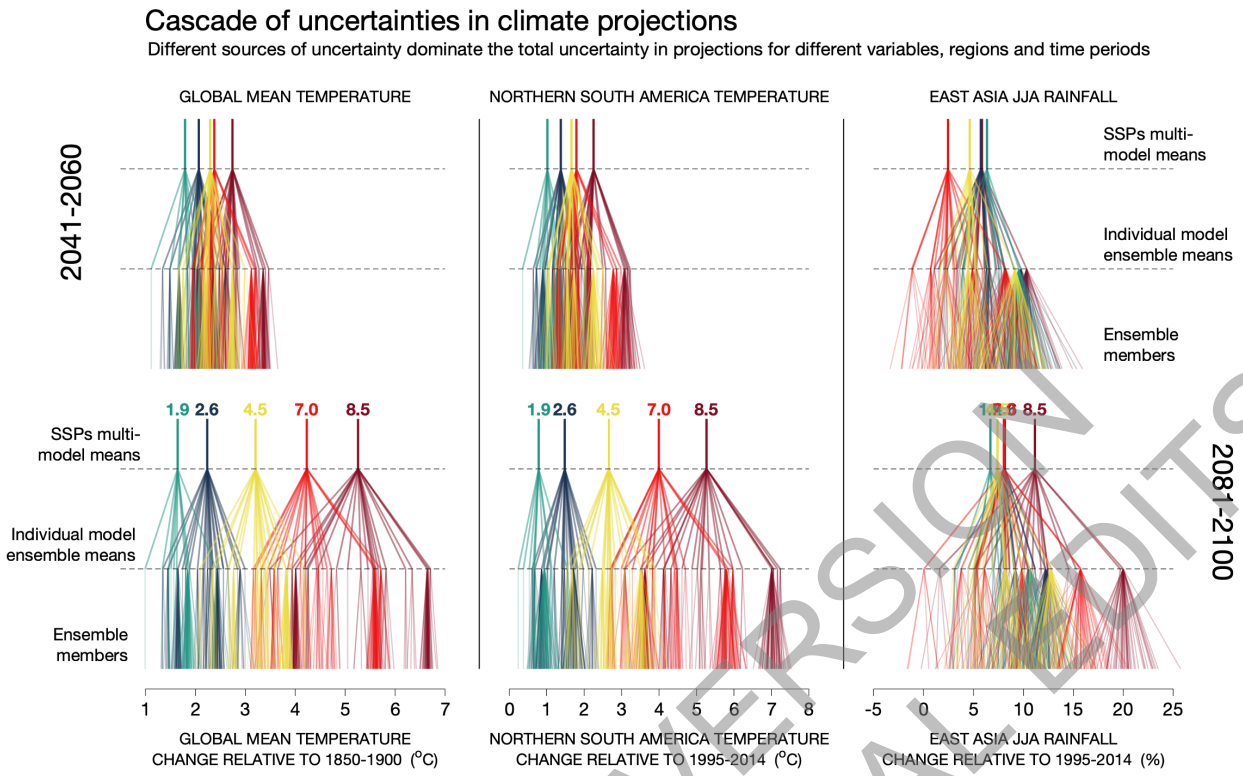

Figure 1.15: The 'cascade of uncertainties' in CMIP6 projections. Changes in GSAT (left), northern South America (region NSA) temperature change (middle), and East Asia (region EAS) summer (JJA) precipitation change (right) are shown for two time periods (2041–2060, top, and 2081–2100, bottom). The SSP-radiative forcing combination is indicated at the top of each cascade at the value of the multi-model mean for each scenario. This branches downwards to show the ensemble mean for each model, and further branches into the individual ensemble members, although often only a single member is available. These diagrams highlight the relative importance of different sources of uncertainty in climate projections, which varies for different time periods, regions and climate variables. See Section 1.4.5 for the definition of the regions used. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

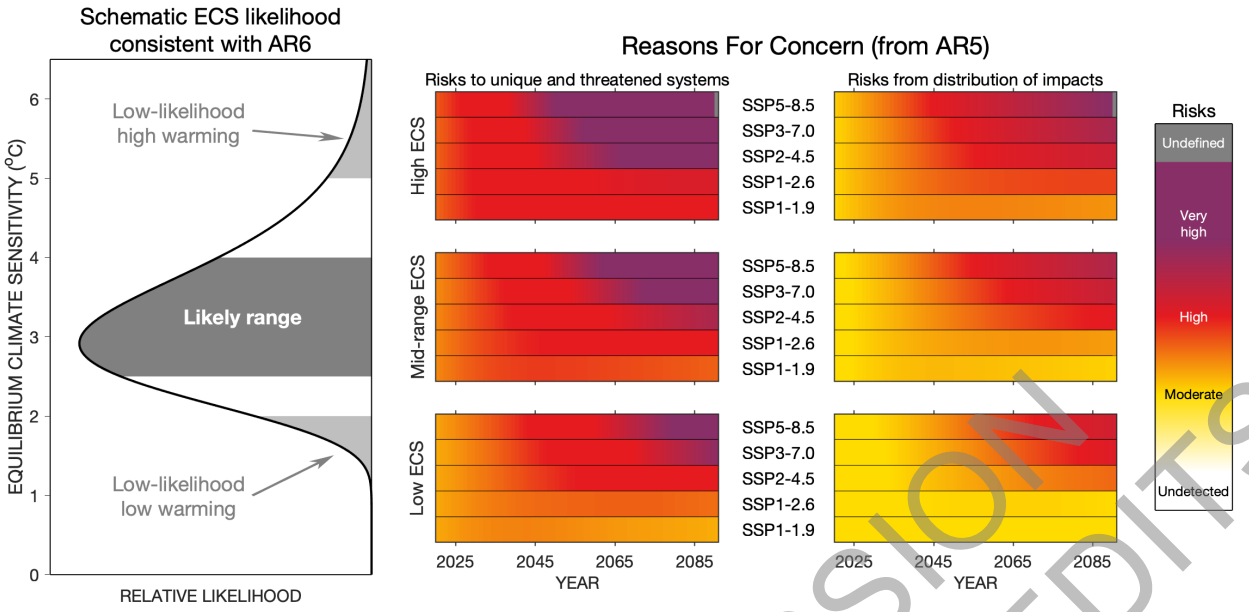

Figure 1.16: Illustrating concepts of low-likelihood scenarios. Left: schematic likelihood distribution consistent with the IPCC AR6 assessments that equilibrium climate sensitivity (ECS) is *likely* in the range 2.5 to 4.0°C, and *very likely* between 2.0 and 5.0°C (Chapter 7). ECS values outside the assessed *very likely* range are designated low-likelihood scenarios in this example (light grey). Middle and right columns: additional risks due to climate change for 2020–2090 using the Reasons For Concern (RFCs, see IPCC, 2014), specifically RFC1 describing the risks to unique and threatened systems and RFC3 describing risks from the distribution of impacts (O'Neill et al., 2017; Zommers et al., 2020). The projected changes of GSAT used are the 95%, median and 5% assessed ranges from Chapter 4 for each SSP (top, middle and bottom); these are designated High ECS, Mid-range ECS and Low ECS respectively. The burning-ember risk spectrum is usually associated with levels of committed GSAT change; instead, this illustration associates the risk spectrum with the GSAT temperature reached in each year from 2020 to 2090. Note that this illustration does not include the vulnerability aspect of each SSP scenario. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

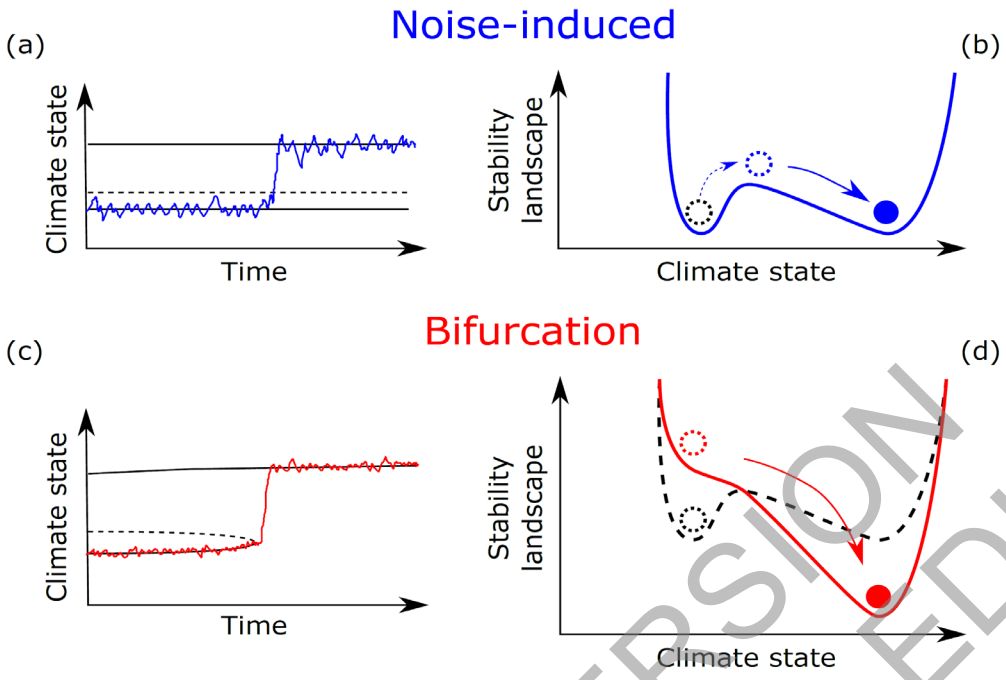
ACCEPTED VERSION SUBJECT TO FINAL EDITS



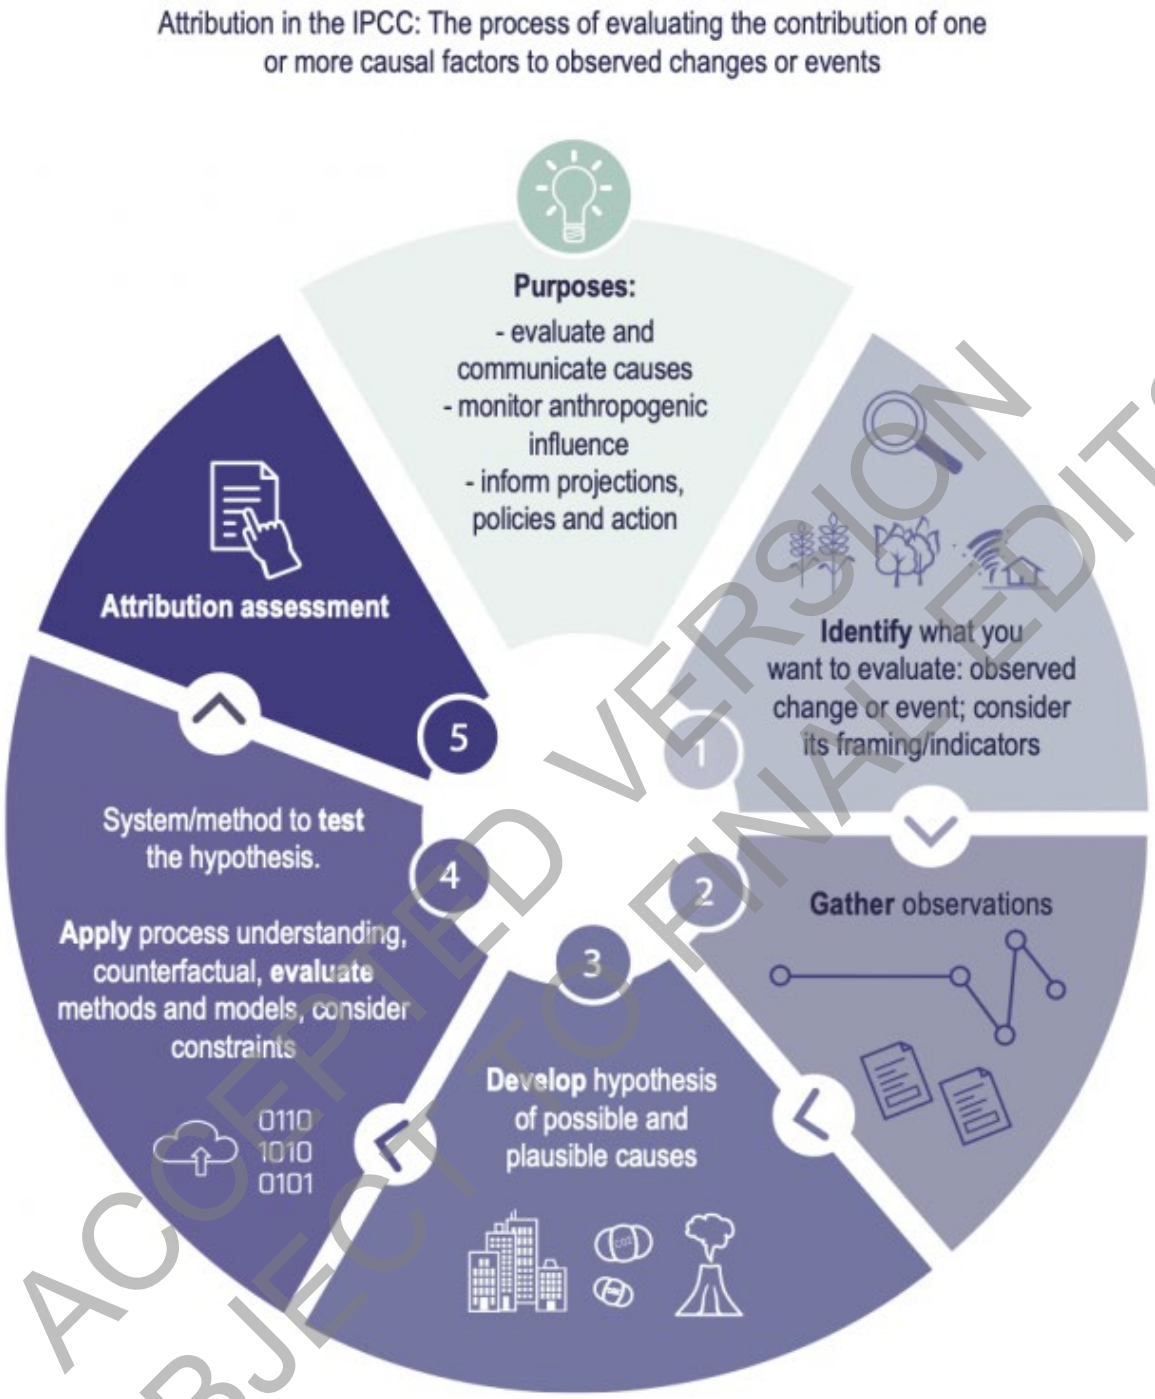


Figure 1.17: Illustration of two types of tipping points: noise-induced (panels a, b) and bifurcation (panels c, d). (a), (c) example time-series (coloured lines) through the tipping point with black solid lines indicating stable climate states (e.g., low or high rainfall) and dashed lines represent the boundary between stable states. (b), (d) stability landscapes provide an intuitive understanding for the different types of tipping point. The valleys represent different climate states the system can occupy, with hill tops separating the stable states. The resilience of a climate state is implied by the depth of the valley. The current state of the system is represented by a ball. Both scenarios assume that the ball starts in the left-hand valley (black dashed lines) and then through different mechanisms dependent on the type of tipping transitions to the right valley (coloured lines). Noise-induced tipping events, for instance drought events causing sudden dieback of the Amazonian rainforest, develop from fluctuations within the system. The stability landscape in this scenario remains fixed and stationary. A series of perturbations in the same direction or one large perturbation are required to force the system over the hill top and into the alternative stable state. Bifurcation tipping events, such as a collapse of the thermohaline circulation in the Atlantic Ocean under climate change, occur when a critical level in the forcing is reached. Here the stability landscape is subjected to a change in shape. Under gradual anthropogenic forcing the left valley begins to shallow and eventually vanishes at the tipping point, forcing the system to transition to the right-hand valley.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Working Group Box: Attribution, Figure 1: **Schematic of the steps to develop an attribution assessment, and the purposes of such assessments.** Methods and systems used to test the attribution hypothesis or theory include model-based fingerprinting, other model-based methods, evidence-based fingerprinting, process-based approaches, empirical or decomposition methods and the use of multiple lines of evidence. Many of the methods are based on the comparison of the observed state of a system to a hypothetical counterfactual world that does not include the driver of interest to help estimate the causes of the observed response.

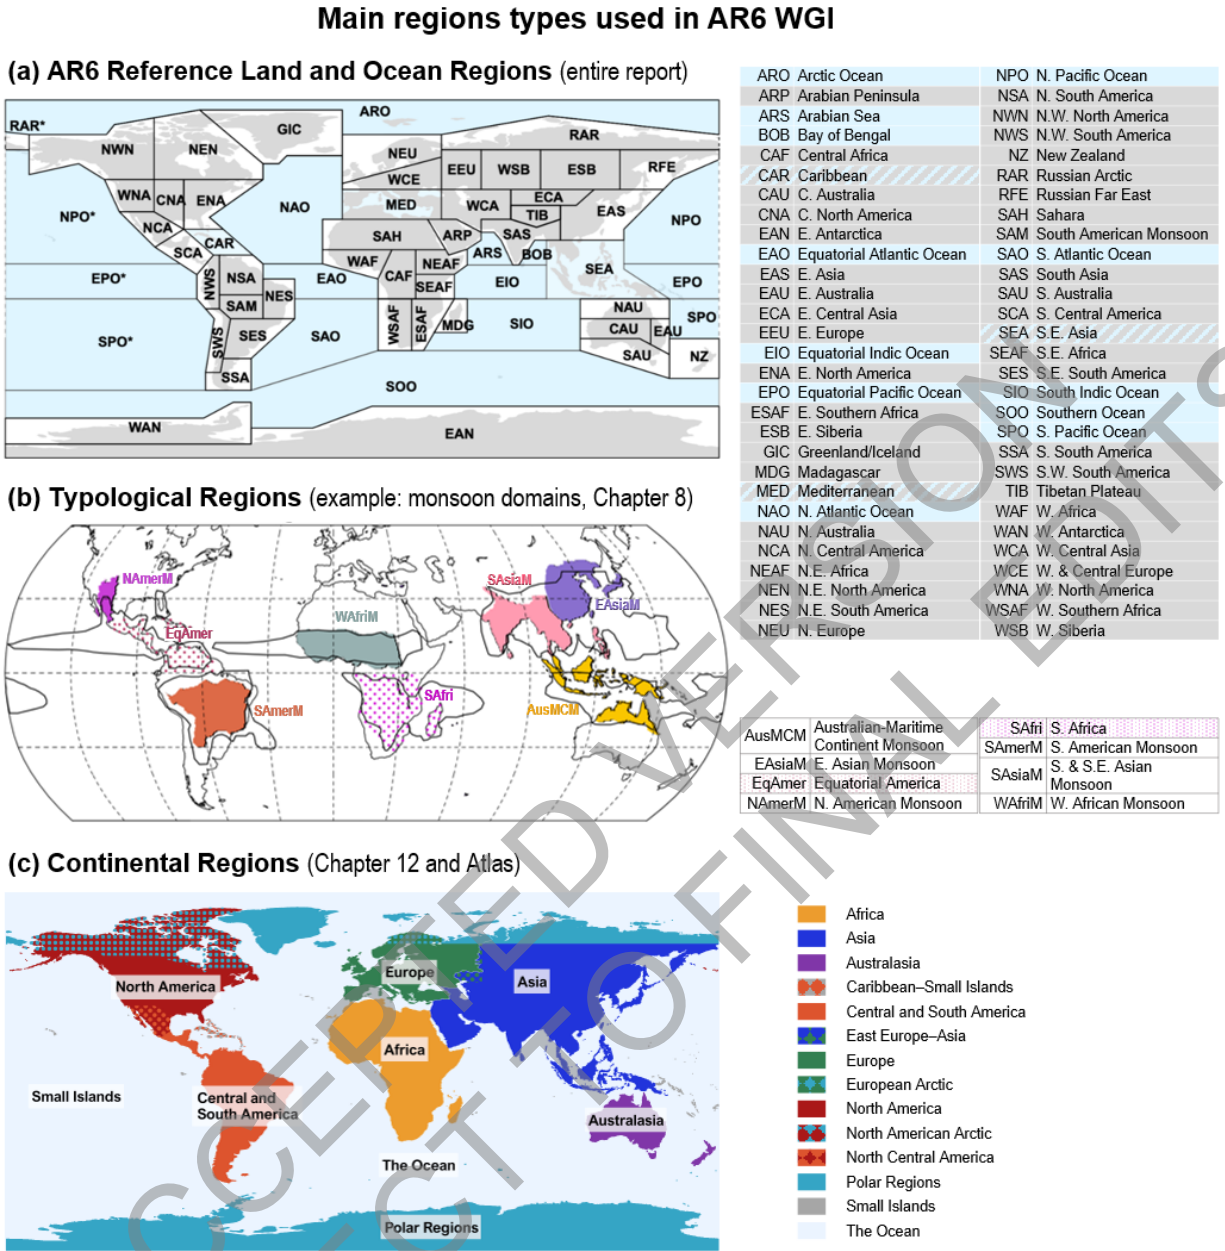

Figure 1.18: Main types of regions used in this report. (a) AR6 WGI Reference Set of Land and Ocean Regions (Iturbide et al., 2020), consisting of 46 land regions and 15 ocean regions, including 3 hybrid regions (CAR, MED, SEA) that are both land and ocean regions. Acronyms are explained on the right of the map. Notice that RAR, SPO, NPO and EPO extend beyond the 180º meridian, therefore appearing at both sides of the map (indicated by dashed lines). A comparison with the previous reference regions of AR5 WGI (IPCC, 7777) is presented in the Atlas. (b) Example of typological regions: monsoon domains adopted in Chapter 8. Acronyms are explained on the right of the map. The black contour lines represent the global monsoon zones, while the coloured regions denote the regional monsoon domains. The two stippled regions (EqAmer and SAfri) do receive seasonal rainfall, but their classification as monsoon regions is still under discussion. (c) Continental Regions used mainly in Chapter 12 and the Atlas. Stippled zones define areas that are assessed in both regions (e.g., the Caribbean is assessed as Small Islands and also as part of Central America). Small Islands are ocean regions containing small islands with consistent climate signals and/or climatological coherence.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

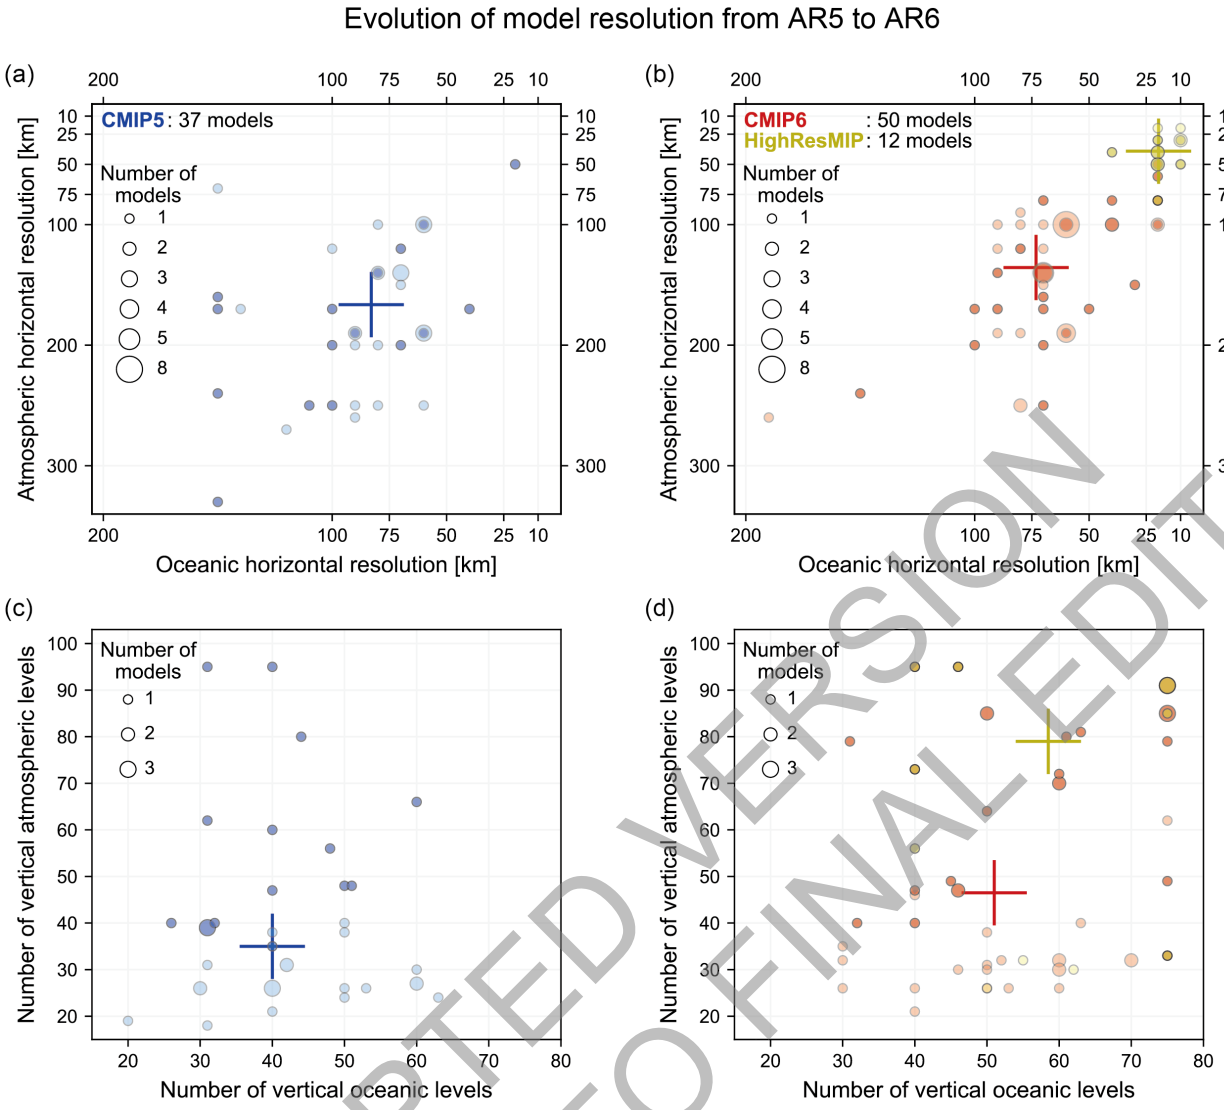

Figure 1.19: Resolution of the atmospheric and oceanic components of global climate models participating in CMIP5, CMIP6, and HighResMIP: (a) (b) horizontal resolution (km), and (c) (d) number of vertical levels. Darker colour circles indicate high-top models (whose top of the atmosphere is above 50 km). The crosses are the median values. These models are documented in Annex II. Note that duplicated models in a modelling group are counted as one entry when their horizontal and vertical resolutions are same. For HighResMIP, one atmosphere-ocean coupled model with the highest resolution from each modelling group is used. The horizontal resolution (rounded to 10km) is the square root of the number of grid points divided by the surface area of the Earth, or the number of surface ocean grid points divided by the area of the ocean surface, for the atmosphere and ocean respectively.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

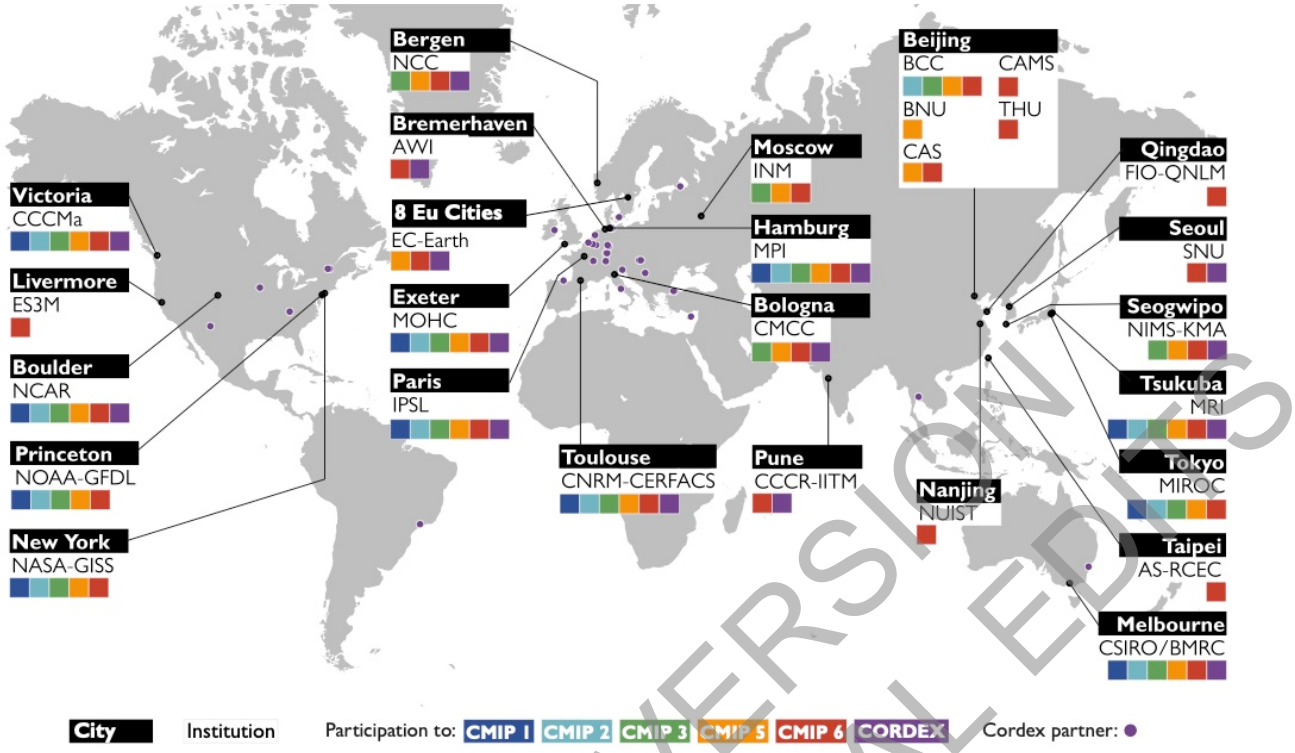

Figure 1.20: A world map showing the increased diversity of modelling centres contributing to CMIP and CORDEX. Climate models are often developed by international consortia. EC-Earth is shown as an example (involving SMHI, Sweden; KNMI, The Netherlands; DMI, Denmark; AEMET, Spain; Met Éireann, Ireland; CNR-ISAC, Italy; Instituto de Meteorologia, Portugal; FMI, Finland), but there are too many such collaborations to display all of them on this map. More complete information about institutions contributing to CORDEX and CMIP6 is found in Annex II.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

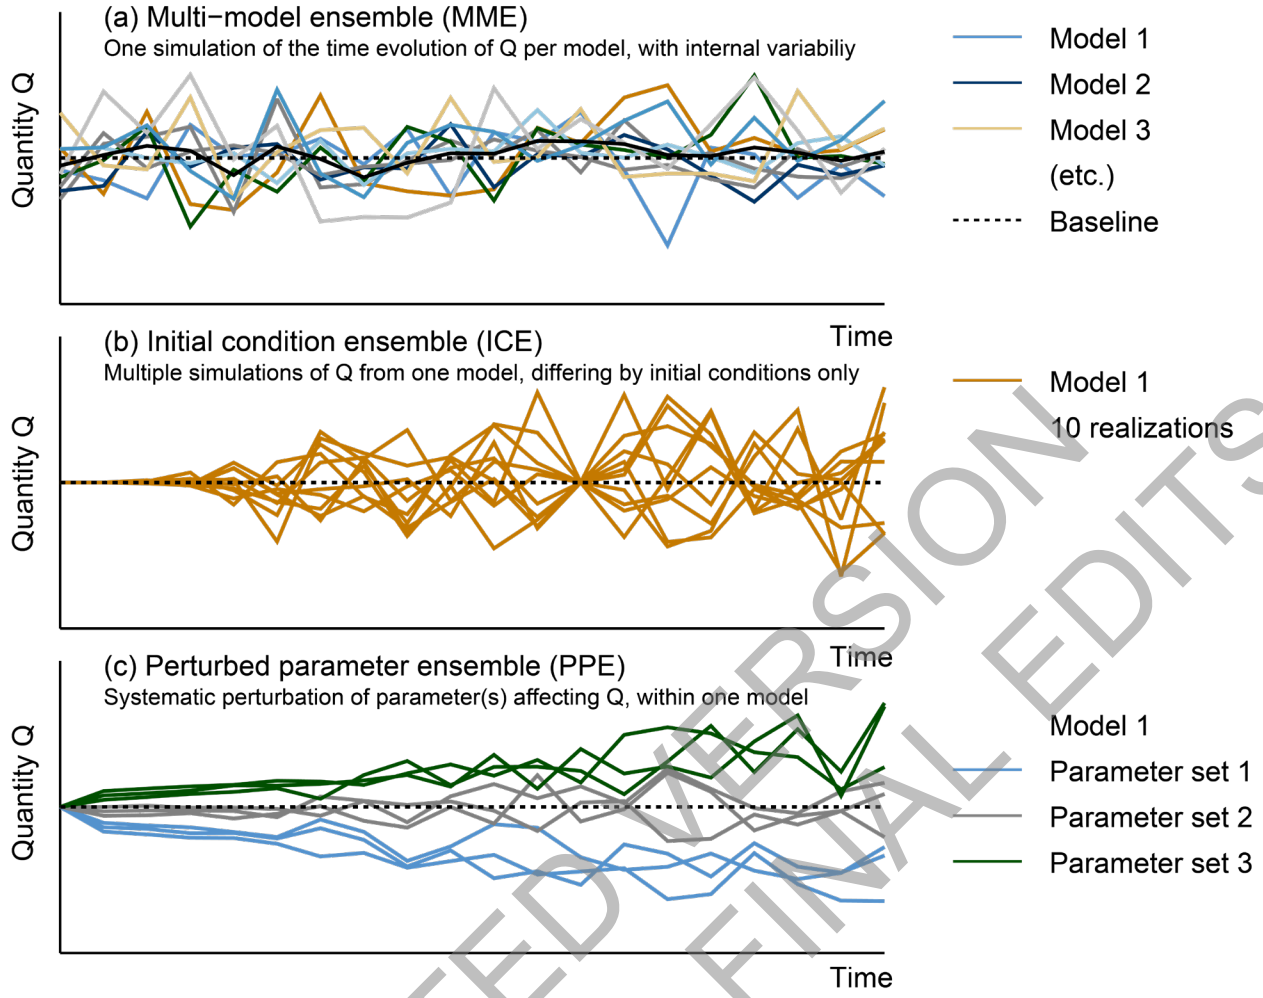

Figure 1.21: Illustration of common types of model ensemble, simulating the time evolution of a quantity Q (such as global mean surface temperature). (a) Multi-model ensemble, where each model has its own realization of the processes affecting Q, and its own internal variability around the baseline value (dashed line). The multi-model mean (black) is commonly taken as the ensemble average. (b) Initial condition ensemble, where several realizations from a single model are compared. These differ only by minute ('micro') perturbations to the initial conditions of the simulation, such that over time, internal variability will progress differently in each ensemble member. (c) Perturbed physics ensemble, which also compares realizations from a single model, but where one or more internal parameters that may affect the simulations of Q are systematically changed to allow for a quantification of the impact of those quantities on the model results. Additionally, each parameter set may be taken as the starting point for an initial condition ensemble. In this figure, each set has three ensemble members.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

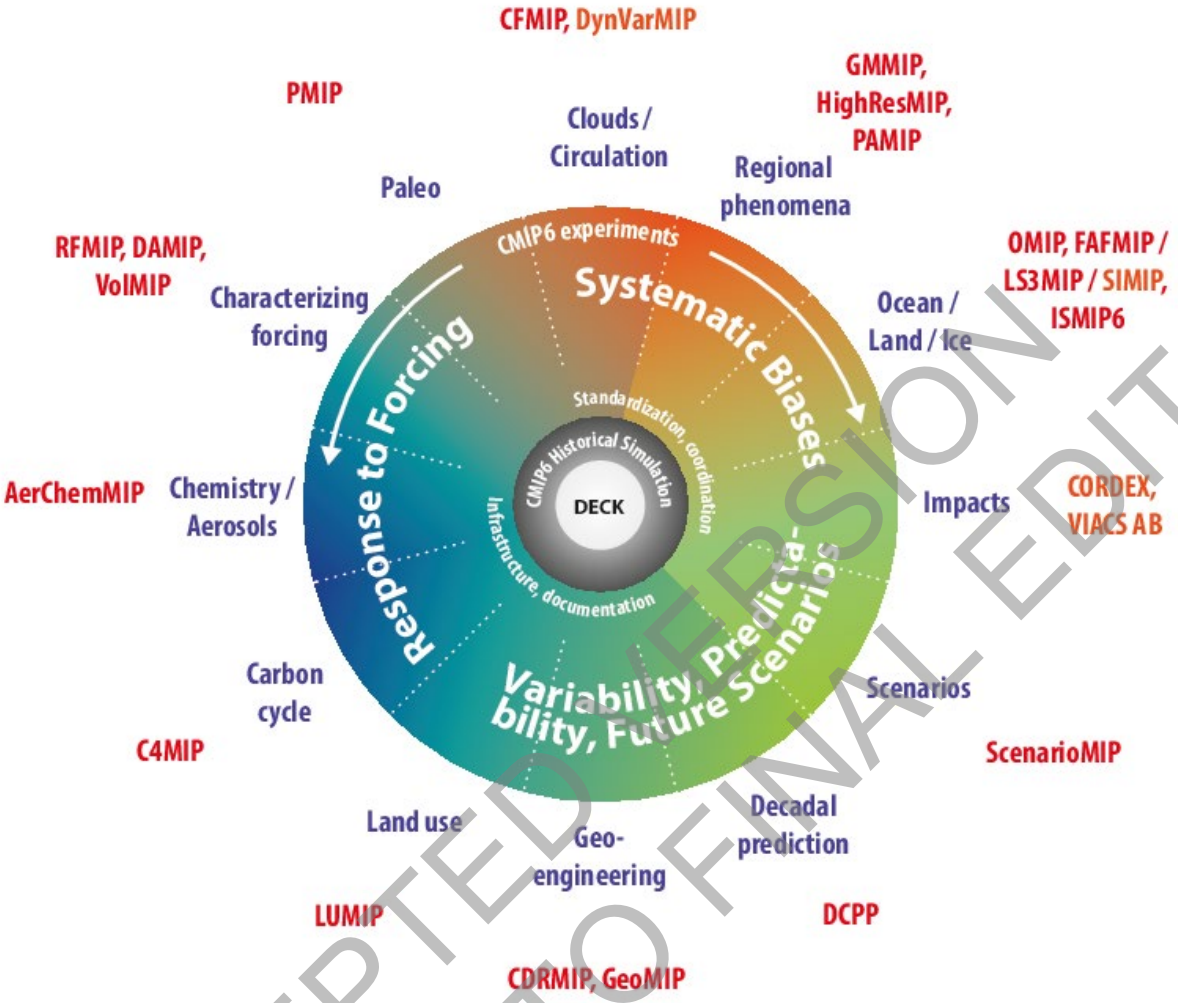

Figure 1.22: Structure of CMIP6, the 6th phase of the Coupled Model Intercomparison Project. The centre shows the common DECK (Diagnostic, Evaluation and Characterization of Klima) and historical experiments that all participating models must perform. The outer circles show the topics covered by the endorsed (blue) and other MIPs (red). See Table 1.3 for explanation of the MIP acronyms. (expanded from Eyring et al., 2016).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

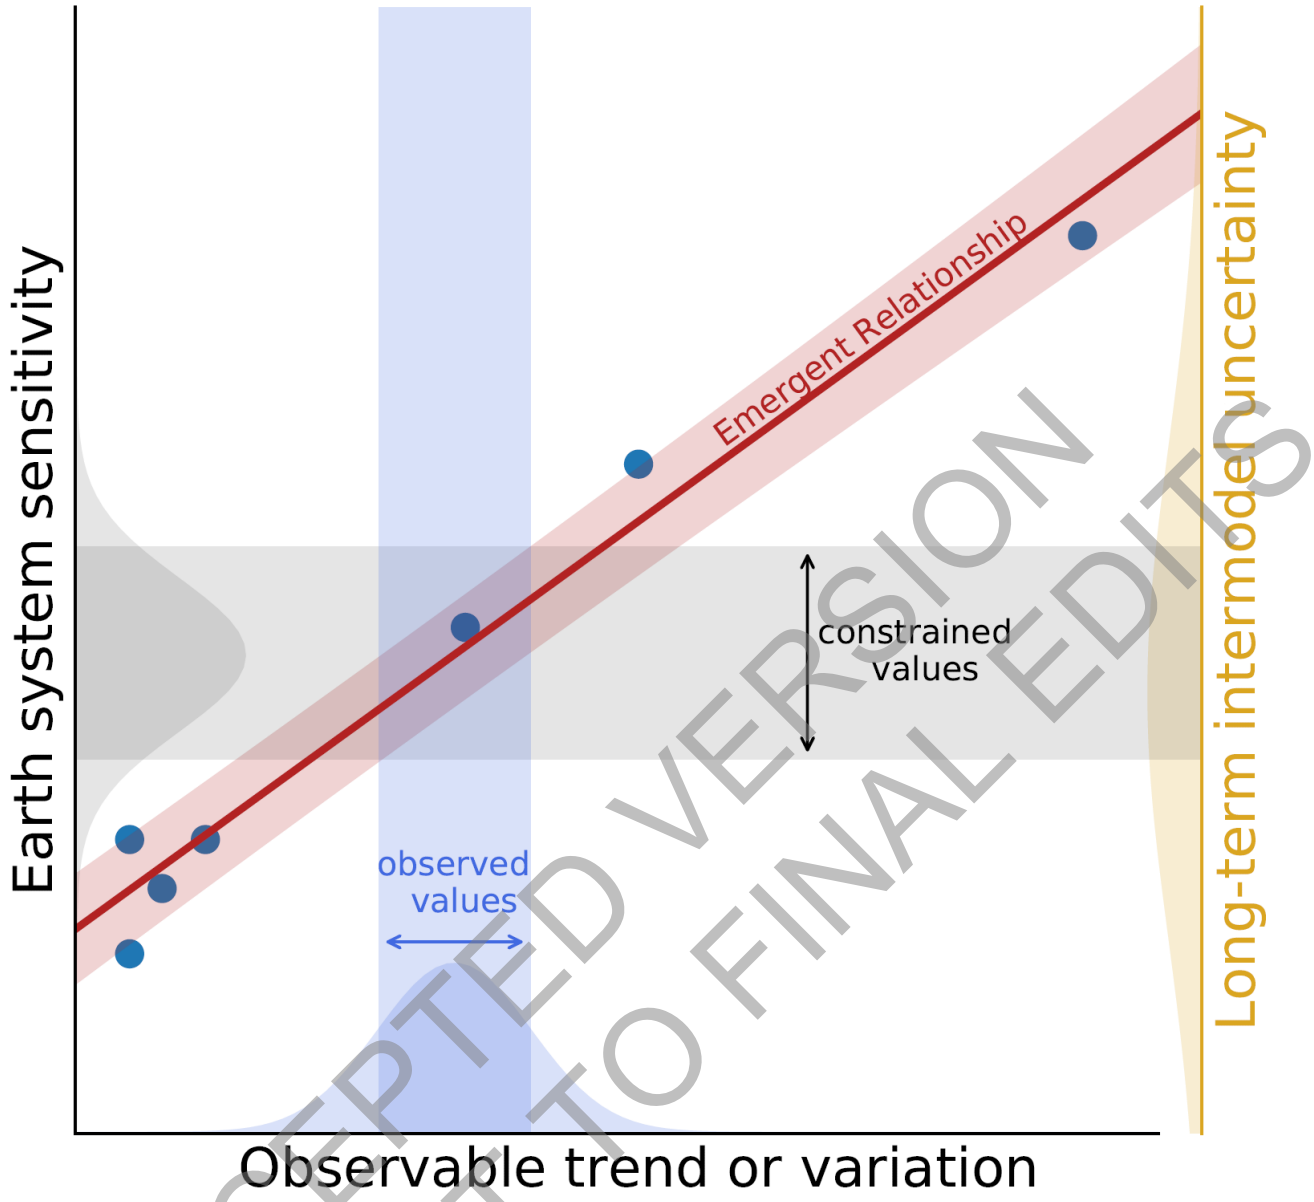

Figure 1.23: The principle of emergent constraints. An ensemble of models (blue dots) defines a relationship between an observable, mean, trend or variation in the climate (x-axis) and an uncertain projection, climate sensitivity or feedback (y-axis). An observation of the x-axis variable can then be combined with the model-derived relationship to provide a tighter estimate of the climate projection, sensitivity or feedback on the y-axis (adapted from Eyring et al. 2019).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

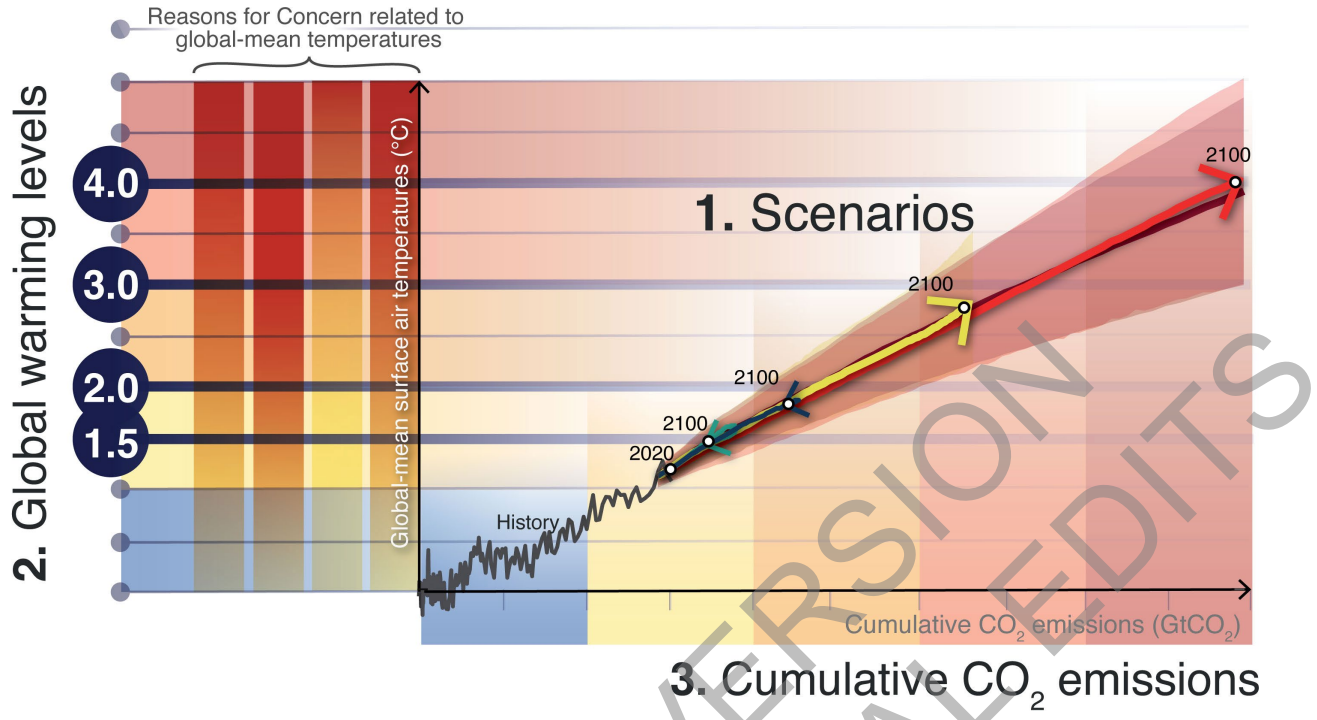

Figure 1.24: The Dimensions of Integration across Chapters and Working Groups in the IPCC AR6 assessment. This report adopts three explicit dimensions of integration to integrate knowledge across chapters and Working Groups. The first dimension is scenarios, the second dimension is global-mean warming levels relative to pre-industrial levels and the third dimension is cumulative CO_2 emissions. For the scenarios, illustrative 2100 end-points are also indicated (white circles). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

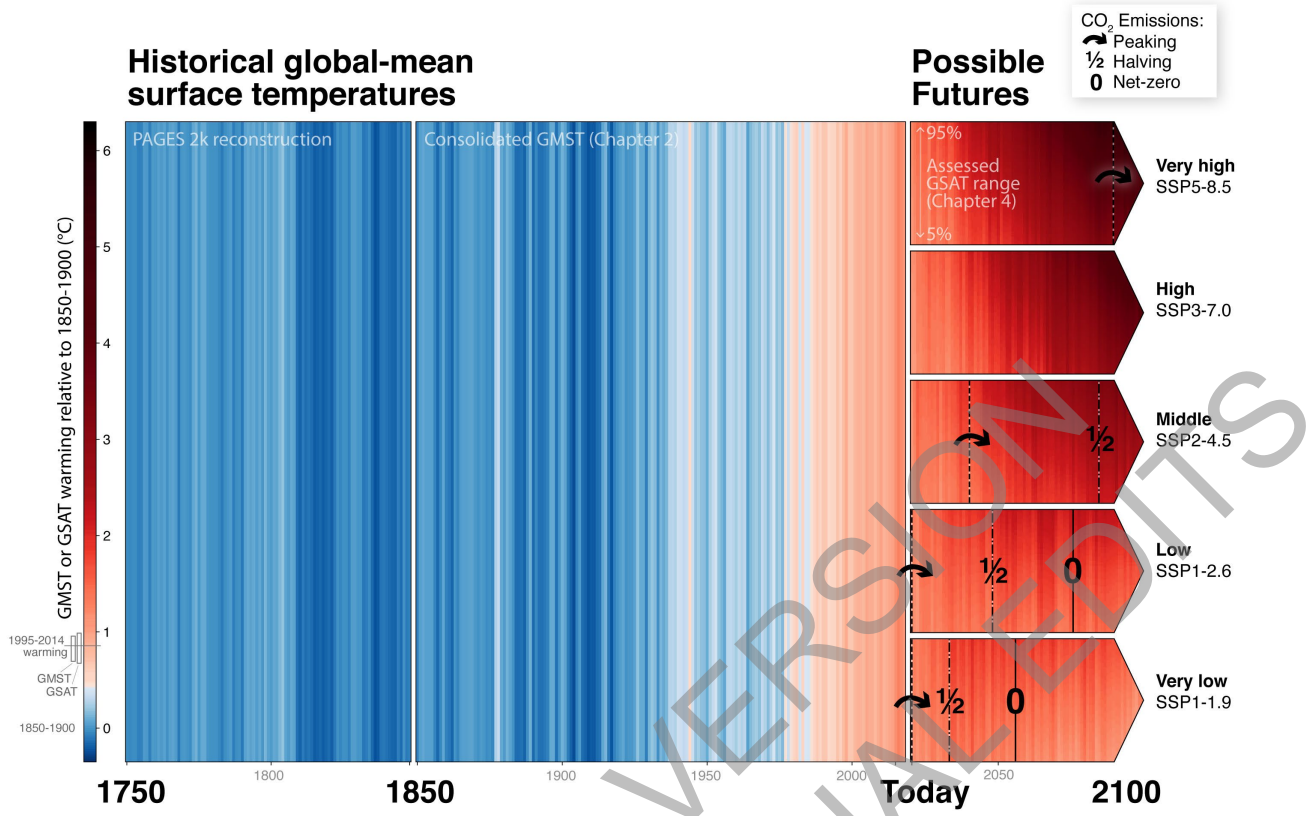

Figure 1.25: Global mean surface air temperature (GSAT) illustrated as warming stripes from blue (cold) to red (warm) over three different time periods. From 1750 to 1850 based on PAGES 2K reconstructions (2017, 2019); from 1850 to 2018 showing the composite GSAT time series assessed in Chapter 2; and from 2020 onwards using the assessed GSAT projections for each Shared Socio-economic Pathway (SSP) (from Chapter 4). For the projections, the upper end of each arrow aligns with colour corresponding to the 95th percentile of the projected temperatures and the lower end aligns with the colour corresponding to the 5th percentile of the projected temperature range. Projected temperatures are shown for five scenarios from 'very low' SSP1-1.9 to 'very high' SSP5-8.5 (see Cross-Chapter Box 1.4 for more details on the scenarios). For illustrative purposes, natural variability has been added from a single CMIP6 Earth system model (MRI ESM2). The points in time when total CO_2 emissions peak, reach halved levels of the peak and reach net-zero emissions are indicated with arrows, '½' and '0' marks, respectively. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

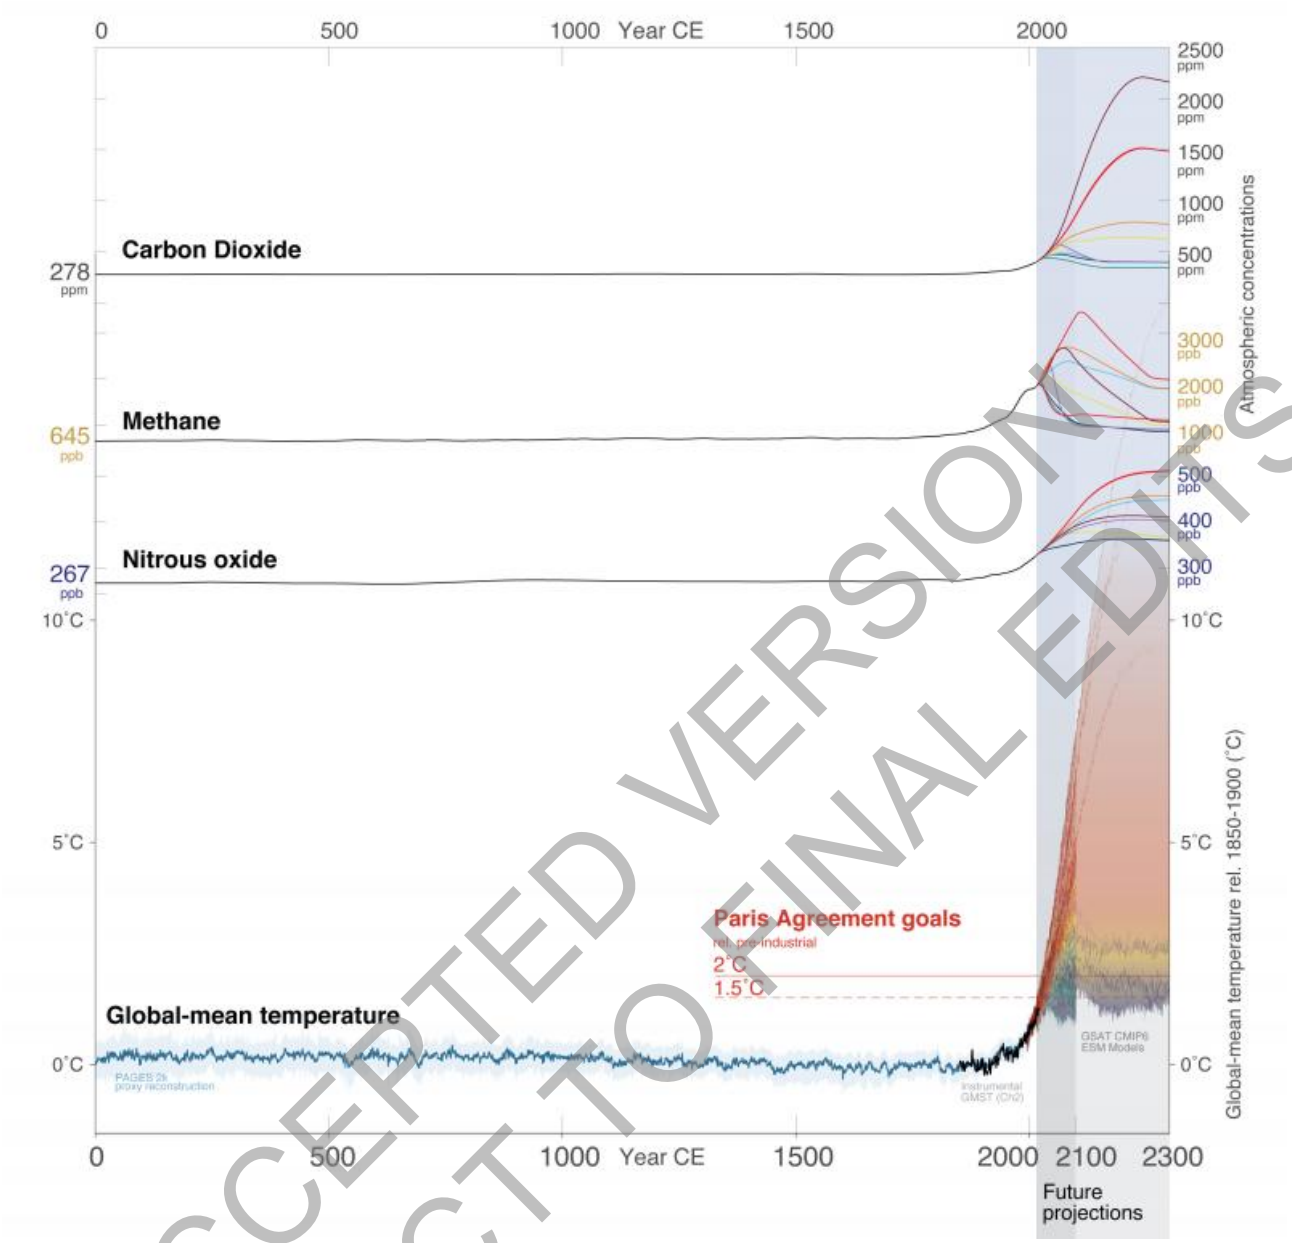
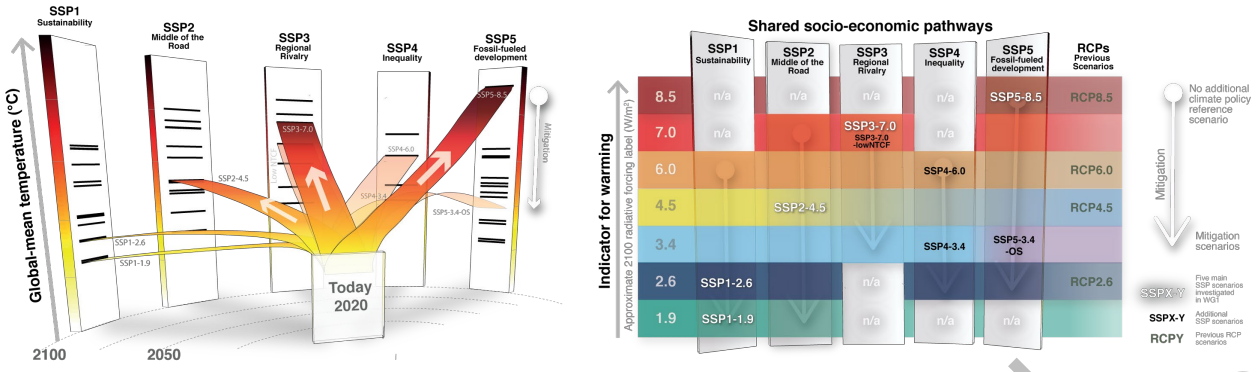
ACCEPTED VERSION SUBJECT TO FINAL EDITS





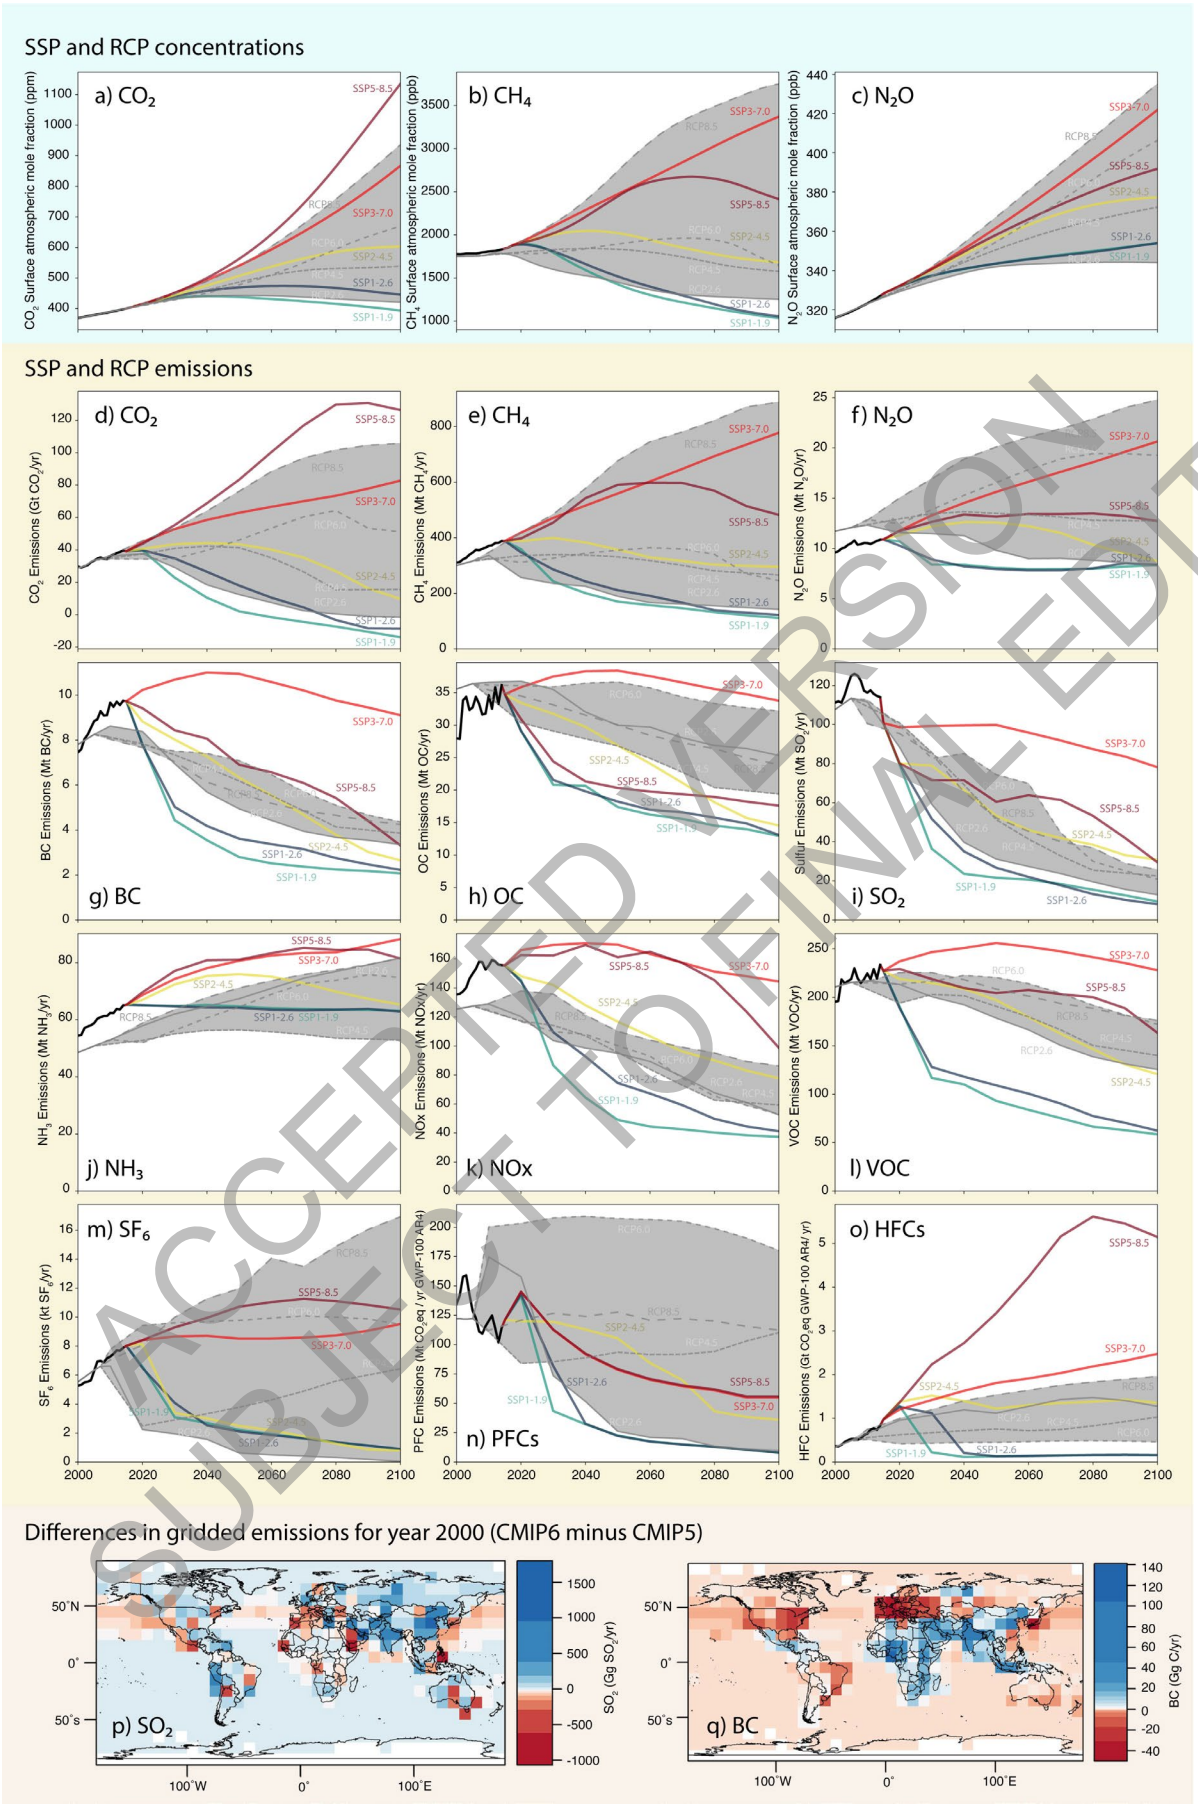


Figure 1.26: Historical and projected future concentrations of CO_2, CH_4 and N_2O and global mean temperatures (GMST). GMST temperature reconstructions over the last 2000 years were compiled by the PAGES 2k Consortium (2017, 2019) (grey line, with 95% uncertainty range), joined by historical GMST timeseries assessed in Chapter 2 (black line) – both referenced against the 1850-1900 period. Future GSAT temperature projections are from CMIP6 ESM models across all concentration-driven SSP scenario projections (Chapter 4). The discontinuity around year 2100 for CMIP6 temperature projections results from the fact that not all ESM models ran each scenario past 2100. The grey vertical band indicates the future 2015-2300 period. The concentrations used to drive CMIP6 Earth System Models are derived from ice core, firn and instrumental datasets (Meinshausen et al., 2017) and projected using an emulator (Cross-Chapter Box 7.1 in Chapter 7; Meinshausen et al., 2020). The colours of the lines indicate the SSP scenarios used in this report (see Cross-Chapter Box 1.4, Figure 1). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Chapter Box 1.4, Figure 1: The SSP scenarios used in this report, their indicative temperature evolution and radiative forcing categorization, and the five socio-economic storylines upon which they are built. The core set of scenarios used in this report, i.e., SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5, is shown together with an additional four SSPs that are part of ScenarioMIP, as well as previous RCP scenarios. In the left panel, the indicative temperature evolution is shown (adapted from Meinshausen et al., 2020). The black stripes on the respective scenario family panels on the left side indicate a larger set of IAM-based SSP scenarios that span the scenario range more fully, but are not used in this report. The SSP-radiative forcing matrix is shown on the right, with the SSP socioeconomic narratives shown as columns and the indicative radiative forcing categorisation by 2100 shown as rows. Note that the descriptive labels for the five SSP narratives refer mainly to the reference scenario futures without additional climate policies. For example, SSP5 can accommodate strong mitigation scenarios leading to net-zero emissions; these do not match a 'fossil-fueled development' label. Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Chapter Box 1.4, Figure 2: Comparison between the Shared Socio-economic Pathways (SSP) scenarios and the Representative Concentration Pathway (RCP) scenarios in terms of their CO_2, CH_4 and N_2O atmospheric concentrations (panels a-c), and their global emissions (panels d-o). Also shown are gridded emission differences for sulfur (panel p) and black carbon (panel q) for the year 2000 between the input emission datasets that underpinned the CMIP5 and CMIP6 model intercomparisons. Historical emission estimates are provided in black in panels d to o. The range of concentrations and emissions investigated under the RCP pathways is grey shaded. Panels p and q adapted from Figure 7 in Hoesly et al. (2018). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

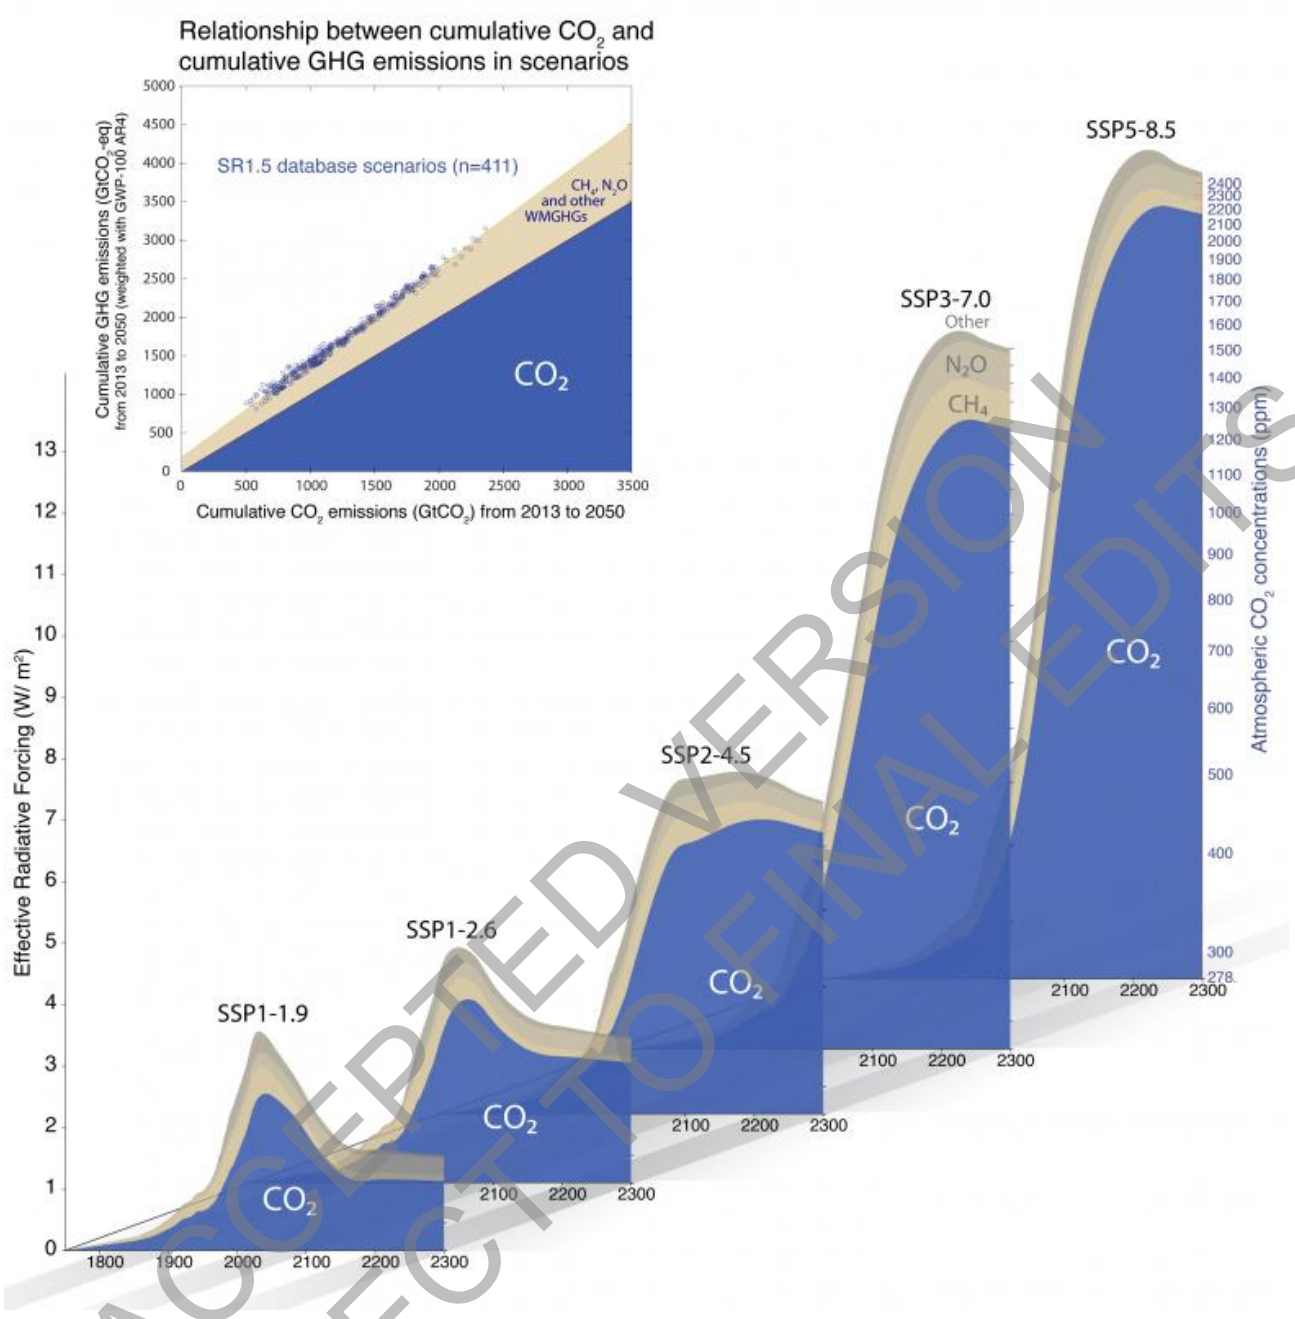

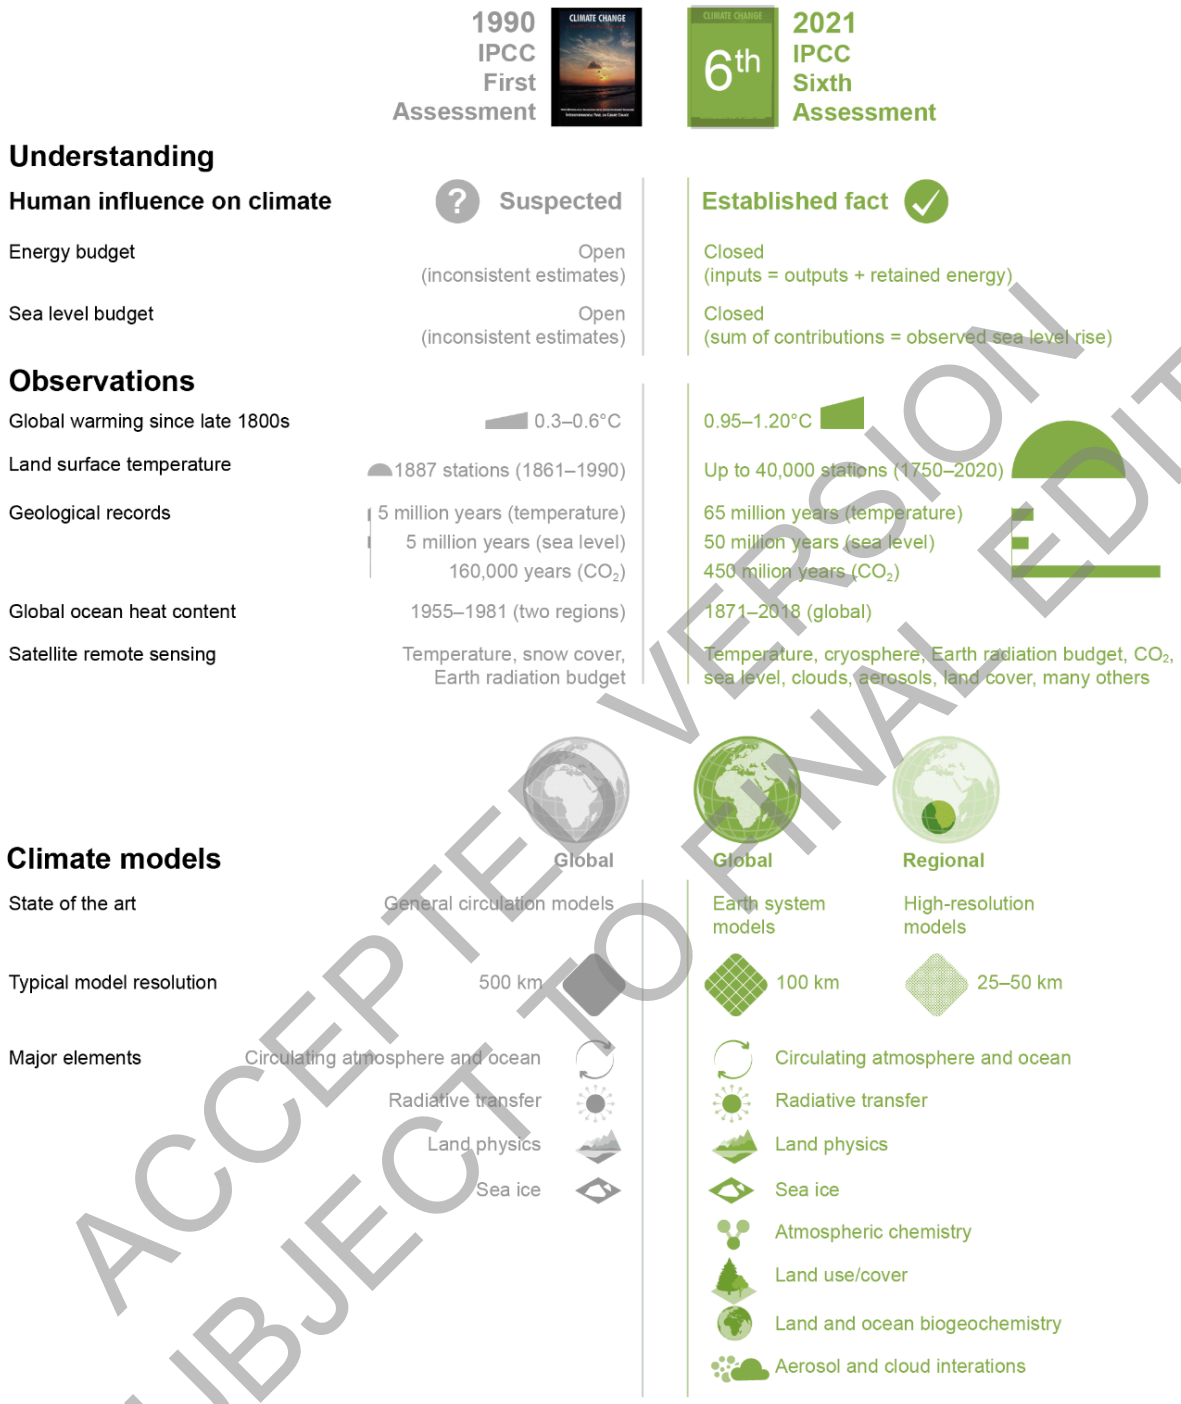

Figure 1.29: The role of CO_2 in driving future climate change in comparison to other greenhouse gases (GHGs). The GHGs included here are CH_4, N_2O, and 40 other long-lived, well-mixed GHGs. The blue shaded area indicates the approximate forcing exerted by CO_2 in Shared Socio-economic Pathways (SSP) scenarios, ranging from very low SSP1-1.9 to very high SSP5-8.5 (Chapter 7). The CO_2 concentrations under the SSP1-1.9 scenarios reach approximately 350 ppm after 2150, while those of SSP5-8.5 exceed 2000 ppm CO_2 in the longer term (through year 2300). Similarly to the dominant radiative forcing share at each point in time (lower area plots), cumulative GWP-100-weighted GHG emissions happen to be closely correlated with cumulative CO_2 emissions, allowing policymakers to make use of the carbon budget concept in a policy context with multi-gas GHG baskets as it exhibits relatively low variation across scenarios with similar cumulative emissions until 2050 (inset panel). Further details on data sources and processing are available in the chapter data table (Table 1.SM.1).

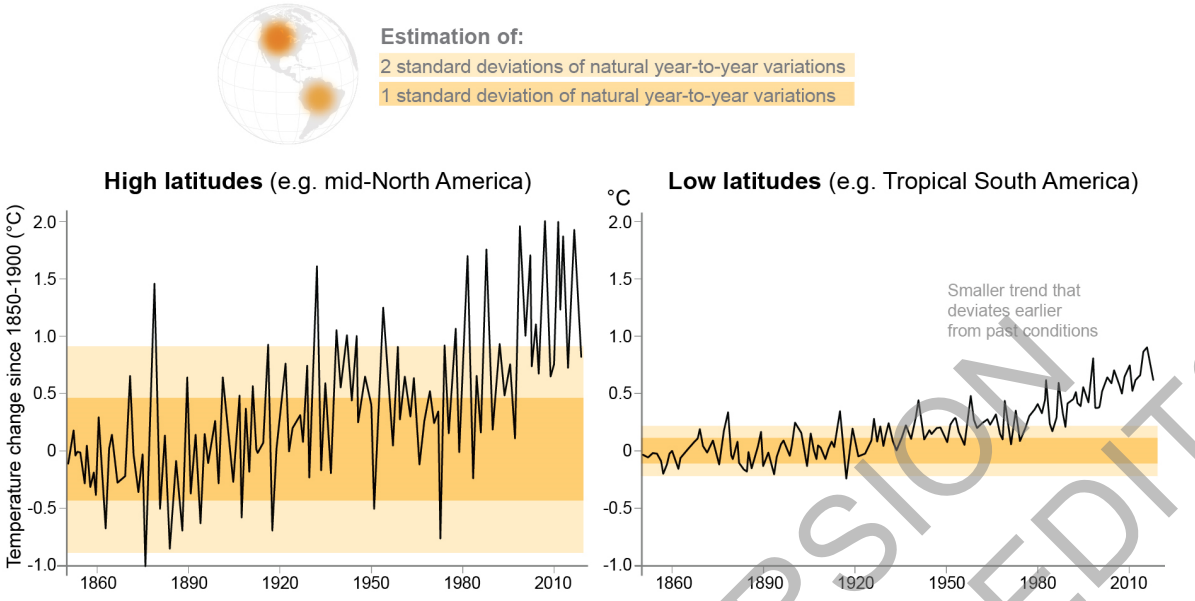
ACCEPTED VERSION SUBJECT TO FINAL EDITS

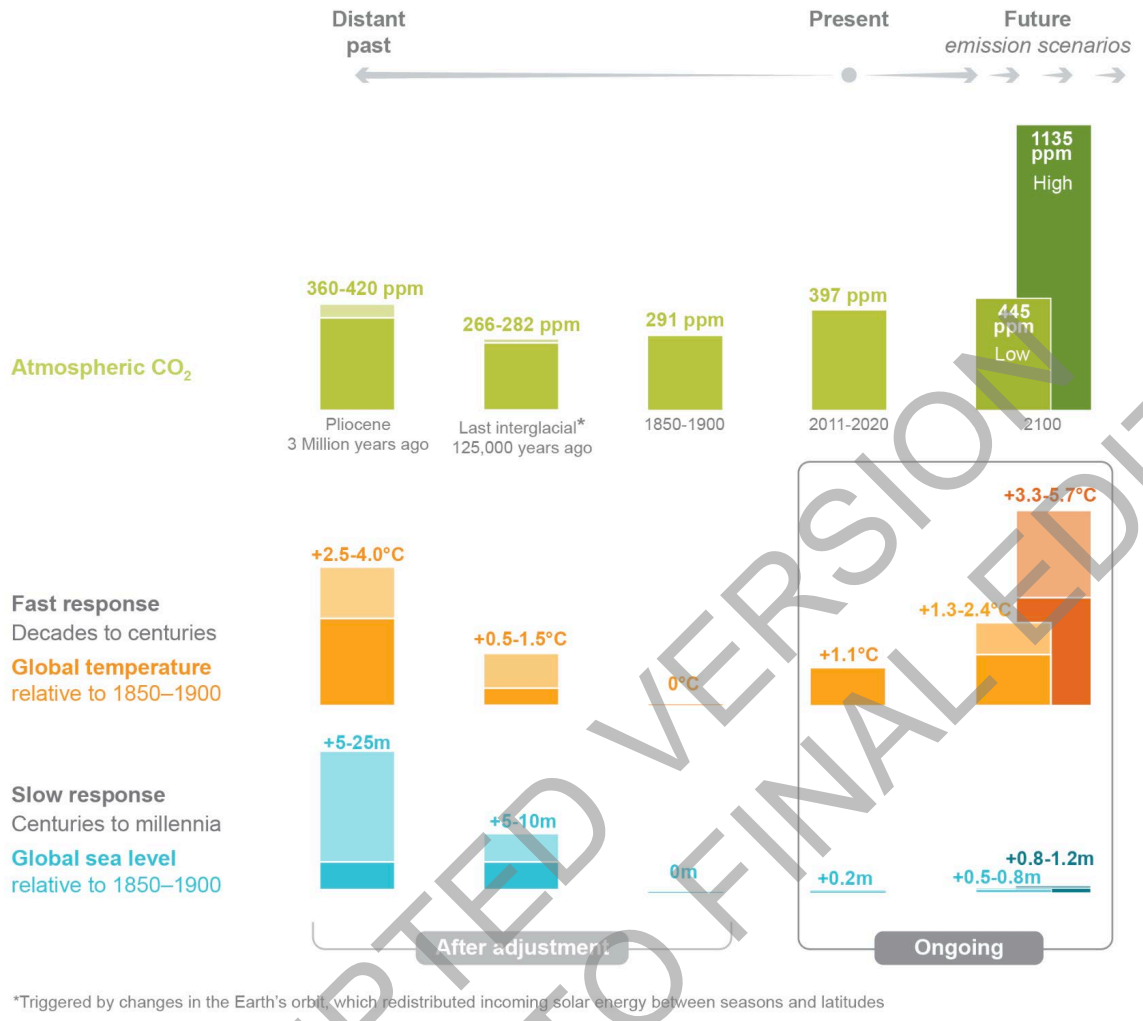
FAQ 1.1: **Do we understand climate change better than when the IPCC started?**

Yes. Between 1990 and 2021, observations, models and climate understanding improved, while the dominant role of human influence in global warming was confirmed.



FAQ 1.1, Figure 1: Sample elements of climate understanding, observations and models as assessed in the IPCC First Assessment Report (1990) and Sixth Assessment Report (2021). Many other advances since 1990, such as key aspects of theoretical understanding, geological records and attribution of change to human influence, are not included in this figure because they are not readily represented in this simple format. Fuller explications of the history of climate knowledge are available in the introductory chapters of the IPCC fourth and sixth Assessment Reports.

ACCEPTED VERSION SUBJECT TO FINAL EDITS



FAQ 1.2: **Where is climate change most apparent?**

Temperature changes are most apparent in regions with smaller natural variations.

FAQ 1.2, Figure 1: **Observed variations in regional temperatures since 1850** (data from Berkeley Earth). Regions in high latitudes, such as mid-North America (40ºN–64ºN, 140ºW–60ºW, left), have warmed by a larger amount than regions at lower latitudes, such as Tropical South America (10ºS–10ºN, 84ºW–16ºW, right), but the natural variations are also much larger at high latitudes (darker and lighter shading represents 1 and 2 standard deviations, respectively, of natural year-to-year variations). The signal of observed temperature change emerged earlier in Tropical South America than mid-North America even though the changes were of a smaller magnitude. (Note that those regions were chosen because of the longer length of their observational record, see Figure 1.14 for more regions).

Table of Contents

Executive Summary **5**

2.1 Introduction **9**

Cross-Chapter Box 2.1: Paleoclimate Reference Periods in the Assessment Report *10*

2.2 Changes in Climate Drivers **12**

2.2.1 Solar and Orbital Forcing *12*

2.2.2 Volcanic Aerosol Forcing *14*

2.2.3 Well-mixed Greenhouse Gases (WMGHGs) *15*

2.2.3.1 CO_2 during 450 Ma to 800 ka 15

2.2.3.2 Glacial-interglacial WMGHG Fluctuations from 800 ka 17

2.2.3.2.1 CO_2 17

2.2.3.2.2 CH_4 18

2.2.3.2.3 N_2O 18

2.2.3.3 Modern measurements of WMGHGs 18

2.2.3.3.1 Carbon Dioxide (CO_2) 20

2.2.3.3.2 Methane (CH_4) 20

2.2.3.3.3 Nitrous Oxide (N_2O) 20

2.2.3.4 Summary of changes in WMGHGs 20

2.2.4 Halogenated Greenhouse Gases (CFCs, HCFCs, HFCs, PFCs, SF6 and others) *21*

2.2.4.1 CFCs 21

2.2.4.2 HCFCs 21

2.2.4.3 HFCs, PFCs, SF6 and other radiatively important halogenated gases 22

2.2.4.4 Summary of changes in halogenated gases 22

2.2.5 Other short-lived gases *23*

2.2.5.1 Stratospheric water vapour 23

2.2.5.2 Stratospheric ozone 23

2.2.5.3 Tropospheric ozone 24

2.2.6 Aerosols *26*

2.2.7 Land use and land cover *27*

2.2.8 Effective radiative forcing (ERF) exerted by the assessed climate drivers *28*

2.3 Changes in large-scale climate **30**

Cross-Chapter Box 2.2: Large-scale indicators of climate change *30*

2.3.1 Atmosphere and Earth's surface *32*

2.3.1.1 Surface temperatures 32

2.3.1.1.1 Temperatures of the deep past (65 Ma to 8 ka) 32

2.3.1.1.2 Temperatures of the post-glacial period (past 7000 years) 34

Cross-Chapter Box 2.3: New estimates of global warming to date and key implications *35*

2.3.1.1.3 Temperatures during the instrumental period – surface 42

2.3.1.2 Temperatures during the instrumental period – free atmosphere 47

2.3.1.2.1 Dataset developments 47

2.3.1.2.2 Assessment of trends 48

2.3.1.3 Global hydrological cycle 50

2.3.1.3.1 Paleo perspective of the global hydrological cycle 50

2.3.1.3.2 Surface humidity 51

2.3.1.3.3 Total column water vapour 52

2.3.1.3.4 Global precipitation 53

2.3.1.3.5 Precipitation minus Evaporation 54

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Executive Summary

Chapter 2 assesses observed large-scale changes in climate system drivers, key climate indicators and principal modes of variability. Chapter 3 considers model performance and detection/attribution, and Chapter 4 covers projections for a subset of these same indicators and modes of variability. Collectively, these chapters provide the basis for later chapters, which focus upon processes and regional changes. Within Chapter 2, changes are assessed from in situ and remotely sensed data and products and from indirect evidence of longer-term changes based upon a diverse range of climate proxies. The time-evolving availability of observations and proxy information dictate the periods that can be assessed. Wherever possible, recent changes are assessed for their significance in a longer-term context, including target proxy periods, both in terms of mean state and rates of change.

Changes in Climate System Drivers

Climate system drivers lead to climate change by altering the Earth's energy balance. The influence of a climate driver is described in terms of its effective radiative forcing (ERF), measured in W m^{-2}. Positive ERF values exert a warming influence and negative ERF values exert a cooling influence (Chapter 7).

Present-day global concentrations of atmospheric carbon dioxide (CO_2) are at higher levels than at any time in at least the past two million years (*high confidence*). Changes in ERF since the late 19th century are dominated by increases in concentrations of greenhouse gases and trends in aerosols; the net ERF is positive and changing at an increasing rate since the 1970s (*medium confidence*). {2.2, 7.2, 7.3}

Change in ERF from natural factors since 1750 is negligible in comparison to anthropogenic drivers (*very high confidence*). Solar activity since 1900 was high but not exceptional compared to the past 9000 years (*high confidence*). The average magnitude and variability of volcanic aerosol forcing since 1900 have not been unusual compared to the past 2500 years (*medium confidence*). {2.2.1, 2.2.2}

In 2019, concentrations of CO_2, methane (CH_4) and nitrous oxide (N_2O) reached levels of 409.9 (±0.4) ppm, 1866.3 (±3.3) ppb and 332.1 (±0.4) ppb, respectively. Since 1850, these well-mixed greenhouse gases (GHGs) have increased at rates that have no precedent on centennial time scales in at least the past 800,000 years. Concentrations of CO_2, CH_4, and N_2O increased from 1750 to 2019 by 131.6 ± 2.9 ppm (47.3%), 1137 ± 10 ppb (156%), and 62 ± 6 ppb (23.0%) respectively. These changes are larger than those between glacial and interglacial periods over the last 800,000 years for CO_2 and CH_4 and of comparable magnitude for N_2O (*very high confidence*). The best estimate of the total ERF from CO_2, CH_4 and N_2O in 2019 relative to 1750 is 2.9 W m^{-2}, an increase of 12.5 % from 2011. ERF from halogenated components in 2019 was 0.4 W m^{-2}, an increase of 3.5% since 2011. {2.2.3, 2.2.4, 7.3.2}

Tropospheric aerosol concentrations across the Northern Hemisphere mid-latitudes increased from 1700 to the last quarter of the 20th century, but have subsequently declined (*high confidence*). Aerosol optical depth (AOD) has decreased since 2000 over Northern Hemisphere mid-latitudes and Southern Hemisphere mid-latitude continents, but increased over South Asia and East Africa (*high confidence*). These trends are even more pronounced in AOD from sub-micrometre aerosols for which the anthropogenic contribution is particularly large. The best-estimate of aerosol ERF in 2019 relative to 1750 is –1.1 W m^{-2}. {2.2.6, 7.3.3}

Changes in other short-lived gases are associated with an overall positive ERF (*medium confidence*). Stratospheric ozone has declined between 60˚S and 60˚N by 2.2% from the 1980s to 2014–2017 (*high confidence*). Since the mid-20th century, tropospheric ozone has increased by 30–70% across the Northern Hemisphere (*medium confidence*). Since the mid-1990s, free tropospheric ozone increases were 2–7% per decade in the northern mid-latitudes (*high confidence*), 2–12% per decade in the tropics (*high confidence*) and <5% per decade in southern mid-latitudes (*medium confidence*). The best estimate of ozone column ERF (0.5 W m^{-2} relative to 1750) is dominated by changes in tropospheric ozone. Due to discrepancies in satellite and in situ records, there is *low confidence* in estimates of stratospheric water vapour change. {2.2.5, 7.3.2}

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Biophysical effects from historical changes in land use have an overall negative ERF (*medium confidence*). The best-estimate ERF from the increase in global albedo is –0.15 W m^{-2} since 1700 and –0.12 W m^{-2} since 1850 (*medium confidence*). {2.2.7, 7.3.4}

Changes in Key Indicators of Global Climate Change

Observed changes in the atmosphere, oceans, cryosphere and biosphere provide unequivocal evidence of a world that has warmed. Over the past several decades, key indicators of the climate system are increasingly at levels unseen in centuries to millennia, and are changing at rates unprecedented in at least the last 2000 years (*high confidence*). In the last decade, global mean surface temperature (GMST) was *more likely than not* higher than for any multi-century average during the Holocene (past 11,700 years) and was comparable to temperatures of the Last Interglacial period (roughly 125,000 years ago). {2.3}

GMST increased by 0.85 [0.69 to 0.95] °C between 1850–1900 and 1995–2014 and by 1.09 [0.95 to 1.20] °C between 1850–1900 and 2011–2020. From 1850–1900 to 2011–2020, the temperature increase over land (1.59 [1.34 to 1.83] °C) has been faster than over the oceans (0.88 [0.68 to 1.01] °C). Over the last 50 years, observed GMST has increased at a rate unprecedented in at least the last 2000 years (*medium confidence*). The increase in GMST since the mid-19th century was preceded by a slow decrease that began in the mid-Holocene (around 6500 years ago) (*medium confidence*). {2.3.1.1, Cross-Chapter Box 2.1}

Changes in GMST and global surface air temperature (GSAT) over time differ by at most 10% in either direction *(high confidence)*, and the long-term changes in GMST and GSAT are presently assessed to be identical. There is expanded uncertainty in GSAT estimates, with the assessed change from 1850–1900 to 1995–2014 being 0.85 [0.67 to 0.98] °C. {Cross-Chapter box 2.3}

The troposphere has warmed since at least the 1950s, and it is *virtually certain* that the stratosphere has cooled. In the Tropics, the upper troposphere has warmed faster than the near-surface since at least 2001, the period over which new observation techniques permit more robust quantification (*medium confidence*). It is *virtually certain* that the tropopause height has risen globally over 1980–2018, but there is *low confidence* in the magnitude. {2.3.1.2}

Changes in several components of the global hydrological cycle provide evidence for overall strengthening since at least 1980 (*high confidence*). However, there is *low confidence* in comparing recent changes with past variations due to limitations in paleoclimate records at continental and global scales. Global land precipitation has *likely* increased since 1950, with a faster increase since the 1980s (*medium confidence*). Near-surface specific humidity has increased over both land (*very likely*) and the oceans (*likely*) since at least the 1970s. Relative humidity has *very likely* decreased over land areas since 2000. Global total column water vapour content has *very likely* increased during the satellite era. Observational uncertainty leads to *low confidence* in global trends in precipitation minus evaporation and river runoff. {2.3.1.3}

Several aspects of the large-scale atmospheric circulation have *likely* changed since the mid-20th century, but limited proxy evidence yields *low confidence* in how these changes compare to longer-term climate. The Hadley circulation has *very likely* widened since at least the 1980s, and extratropical storm tracks have *likely* shifted poleward in both hemispheres. Global monsoon precipitation has *likely* increased since the 1980s, mainly in the Northern Hemisphere (*medium confidence*). Since the 1970s, near-surface winds have *likely* weakened over land. Over the oceans, near-surface winds *likely* strengthened over 1980–2000, but divergent estimates lead to *low confidence* in the sign of change thereafter. It is *likely* that the northern stratospheric polar vortex has weakened since the 1980s and experienced more frequent excursions toward Eurasia. {2.3.1.4}

Current Arctic sea ice coverage levels are the lowest since at least 1850 for both annual mean and late-summer values (*high confidence*) and for the past 1000 years for late-summer values (*medium confidence*). Between 1979 and 2019, Arctic sea ice area has decreased in both summer and winter, with sea ice becoming younger, thinner and more dynamic (*very high confidence*). Decadal means for Arctic sea ice area decreased from 6.23 million km^2 in 1979–1988 to 3.76 million km^2 in 2010–2019 for September and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

from 14.52 to 13.42 million km^2 for March. Antarctic sea ice area has experienced little net change since 1979 (*high confidence*), with only minor differences between sea ice area decadal means for 1979–1988 (2.04 million km^2 for February, 15.39 million km^2 for September) and 2010–2019 (2.17 million km^2 for February, 15.75 million km^2 for September). {2.3.2.1}

Changes across the terrestrial cryosphere are widespread, with several indicators now in states unprecedented in centuries to millennia (*high confidence*). Reductions in spring snow cover extent have occurred across the Northern Hemisphere since at least 1978 (*very high confidence*). With few exceptions, glaciers have retreated since the second half of the 19th century and continued to retreat with increased rates since the 1990s (*very high confidence*); this behaviour is unprecedented in at least the last 2000 years (*medium confidence*). Greenland Ice Sheet mass loss has increased substantially since 2000 (*high confidence*). The Greenland Ice Sheet was smaller than at present during the Last Interglacial period (*high confidence*) and the mid-Holocene (*high confidence*). The Antarctic Ice Sheet (AIS) lost mass between 1992 and 2020 (*very high confidence*), with an increasing rate of mass loss over this period (*medium confidence*). Although permafrost persists in areas of the Northern Hemisphere where it was absent prior to 3000 years ago, increases in temperatures in the upper 30 m over the past three to four decades have been widespread (*high confidence*). {2.3.2}

Global mean sea level (GMSL) is rising, and the rate of GMSL rise since the 20th century is faster than over any preceding century in at least the last three millennia (*high confidence*). Since 1901, GMSL has risen by 0.20 [0.15–0.25] m, and the rate of rise is accelerating. Further back in time, there is *medium confidence* that GMSL was within –3.5 to 0.5 m (*very likely*) of present during the mid-Holocene (6000 years ago), 5 to 10 m (*likely*) higher during the Last Interglacial (125,000 years ago), and 5 to 25 m (*very likely*) higher during the mid-Pliocene Warm Period (MPWP) (3.3 million years ago). {2.3.3.3}

Recent ocean changes are widespread, and key ocean indicators are in states unprecedented for centuries to millennia (*high confidence*). Since 1971, it is *virtually certain* that global ocean heat content has increased for the upper (0–700 m) layer, *very likely* for the intermediate (700–2000 m) layer and *likely* below 2000 m, and is currently increasing faster than at any point since at least the last deglacial transition (18-11 thousand years ago) (*medium confidence*). It is *virtually certain* that large-scale near-surface salinity contrasts have intensified since at least 1950. The Atlantic Meridional Overturning Circulation (AMOC) was relatively stable during the past 8000 years (*medium confidence*) but declined during the 20th century (*low confidence*). Ocean pH has declined globally at the surface over the past four decades (*virtually certain*) and in all ocean basins in the ocean interior (*high confidence*) over the past 2–3 decades. Deoxygenation has occurred in most open ocean regions during the mid 20th to early 21st centuries (*high confidence*), with decadal variability (*medium confidence*). Oxygen minimum zones are expanding at many locations (*high confidence*). {2.3.3}

Changes in the marine biosphere are consistent with large-scale warming and changes in ocean geochemistry (*high confidence*). The ranges of many marine organisms are shifting towards the poles and towards greater depths (*high confidence*), but a minority of organisms are shifting in the opposite directions. This mismatch in responses across species means that the species composition of ecosystems is changing (*medium confidence*). At multiple locations, various phenological metrics for marine organisms have changed in the last 50 years, with the nature of the changes varying with location and with species (*high confidence*). In the last two decades, the concentration of phytoplankton at the base of the marine food web, as indexed by chlorophyll concentration, has shown weak and variable trends in low and mid-latitudes and an increase in high latitudes (*medium confidence*). Global marine primary production decreased slightly from 1998–2018, with increasing production in the Arctic (*medium confidence*). {2.3.4.2}

Changes in key global aspects of the terrestrial biosphere are consistent with large-scale warming (*high confidence*). Over the last century, there have been poleward and upslope shifts in the distributions of many land species (*very high confidence*) as well as increases in species turnover within many ecosystems (*high confidence*). Over the past half century, climate zones have shifted poleward, accompanied by an increase in the length of the growing season in the Northern Hemisphere extratropics and an increase in the amplitude of the seasonal cycle of atmospheric CO_2 above 45°N (*high confidence*). Since the early 1980s, there has been a global-scale increase in the greenness of the terrestrial surface (*high confidence*). {2.3.4.1,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.3.4.3}

During the Mid-Pliocene warm period (MPWP, 3.3–3.0 million years ago) slowly changing large-scale indicators reflect a world that was warmer than present, with CO_2 similar to current levels. CO_2 levels during the MPWP were similar to present for a sustained period, within a range of 360–420 ppm (*medium confidence*). Relative to the present, GMST, GMSL and precipitation rate were all higher, the Northern Hemisphere latitudinal temperature gradient was lower, and major terrestrial biomes were shifted northward (*very high confidence*). There is *high confidence* that cryospheric indicators were diminished and *medium confidence* that the Pacific longitudinal temperature gradient weakened and monsoon systems strengthened. {2.3, Cross-Chapter Box 2.4, 9.6.2}

Inferences from past climate states based on proxy records can be compared with climate projections over coming centuries to place the range of possible futures into a longer-term context. There is *medium confidence* in the following mappings between selected paleo periods and future projections: During the Last Interglacial, GMST is estimated to have been 0.5°C–1.5°C warmer than the 1850–1900 reference for a sustained period, which overlaps the low end of the range of warming projected under SSP1-2.6, including its negative-emissions extension to the end of the 23rd century [1.0–2.2] °C. During the mid-Pliocene Warm Period, the GMST estimate [2.5-4.0] °C is similar to the range projected under SSP2-4.5 for the end of the 23rd century [2.3-4.6] °C. GMST estimates for the Miocene Climatic Optimum [5–10] °C and Early Eocene Climatic Optimum [10–18] °C, about 15 and 50 million years ago, respectively, overlap with the range projected for the end of the 23rd century under SSP5-8.5 [6.6–14.1] °C. {Cross-Chapter Box 2.1, 2.3.1, 4.3.1.1, 4.7.1.1}

Changes in Modes of Variability

Since the late 19th century, major modes of climate variability show no sustained trends but do exhibit fluctuations in frequency and magnitude at inter-decadal time scales, with the notable exception of the Southern Annular Mode, which has become systematically more positive (*high confidence*). There is *high confidence* that these modes of variability have existed for millennia or longer, but *low confidence* in detailed reconstructions of most modes prior to direct instrumental records. Both polar annular modes have exhibited strong positive trends toward increased zonality of midlatitude circulation over multi-decadal periods, but these trends have not been sustained for the Northern Annular Mode since the early 1990s (*high confidence*). For tropical ocean modes, a sustained shift beyond multi-centennial variability has not been observed for El Niño–Southern Oscillation (*medium confidence*), but there is *low evidence* and *low agreement* about the long-term behaviour of other tropical ocean modes. Modes of decadal and multi-decadal variability over the Pacific and Atlantic oceans exhibit no significant trends over the period of observational records (*high confidence*). {2.4}

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.1 Introduction

This chapter assesses the evidence-basis for large-scale past changes in selected components of the climate system. As such, it combines much of the assessment performed in Chapters 2 through 5 of the Fifth Assessment Report (AR5) WGI contribution (IPCC, 2013) that, taken together, supported a finding of unequivocal recent warming of the climate system. The Sixth Assessment Report (AR6) WGI Report structure differs substantially from that in AR5 (Section 1.1.2). The current chapter focuses upon observed changes in climate system drivers and changes in key selected large-scale indicators of climate change and in important modes of variability (Cross-Chapter Box 2.2), which allow for an assessment of changes in the global climate system in an integrated manner. This chapter is complemented by Chapters 3 and 4, which respectively consider model assessment / detection and attribution, and future climate projections for subsets of these same indicators and modes. It does not consider changes in observed extremes, which are assessed in Chapter 11. The chapter structure is outlined in the visual abstract (Figure 2.1).

[START FIGURE 2.1 HERE]

Figure 2.1: Chapter 2 visual abstract of contents.

[END FIGURE 2.1 HERE]

Use is made of paleoclimate, in situ, ground- and satellite-based remote sensing, and reanalysis data products where applicable (Section 1.5). All observational products used in the chapter are detailed in Annex I, and information on data sources and processing for each figure and table can be found in the associated chapter table 2.SM.1 available as an electronic supplement to the chapter. Use of common periods ranging from 56 million years ago through to the recent past is applied to the extent permitted by available data (Section 1.4.1 and Cross-Chapter Box 2.1). In all cases, the narrative proceeds from as far in the past as the data permit through to the present. Each sub-section starts by highlighting the key findings from AR5 and any relevant AR6-cycle special reports (SROCC, SR1.5, SRCCL), and then outlines the new evidence-basis arising from a combination of: i) new findings reported in the literature, including new datasets and new versions of existing datasets; and ii) recently observed changes, before closing with a new summary assessment.

Trends, when calculated as part of this assessment, have wherever possible been calculated using a common approach following that adopted in Box 2.2 of Chapter 2 of AR5 (Hartmann et al., 2013). In addition to trends, consideration is also made of changes between various time slices / periods in performing the assessment (Section 1.4.1 and Cross-Chapter Box 2.1). Statistical significance of trends and changes are assessed at the two-tailed 90% confidence (*very likely*) level unless otherwise stated. Limited use is also made of published analyses that have employed a range of methodological choices. In each such case the method / metric is stated.

There exist a variety of inevitable and, in some cases, irreducible uncertainties in performing an assessment of the observational evidence for climate change. In some instances, a combination of sources of uncertainty is important. For example, the assessment of global surface temperature over the instrumental record in Section 2.3.1.1.3 considers a combination of observational-dataset and trend-estimate uncertainties. Furthermore, estimates of parametric uncertainty are often not comprehensive in their consideration of all possible factors and, when such estimates are constructed in distinct manners, there are often significant limitations to their direct comparability (Hartmann et al., 2013; their Box 2.1).

Cross-Chapter Box 2.1: Paleoclimate Reference Periods in the Assessment Report

Contributing Authors: Darrell Kaufman (USA), Kevin Burke (USA), Samuel Jaccard (Switzerland), Chris Jones (UK), Wolfgang Kiessling (Germany), Daniel Lunt (UK), Olaf Morgenstern (New Zealand), John W. Williams (USA)

Over the long evolution of the Earth's climate system, several periods have been extensively studied as examples of distinct climate states. This Cross-Chapter Box places multiple paleoclimate reference periods into the unifying context of Earth's long-term climate history, and points to sections in the report with additional information about each period. Other reference periods, including those of the industrialized era, are described in Section 1.4.1.

The reference periods represent times that were both colder and warmer than present, and periods of rapid climate change, many with informative parallels to projected climate (Cross-Chapter Box 2.1, Table 1). They are used to address a wide variety of questions related to natural climate variations in the past (FAQ 1.3). Most of them are used as targets to evaluate the performance of climate models under different climate forcings (Section 3.8.2), while also providing insight into the ocean-atmospheric circulation changes associated with various radiative forcings and geographical changes.

Global Mean Surface Temperature (GMST) is a key indicator of the changing state of the climate system. Earth's mean temperature history during the current geological era (Cenozoic, beginning 66 Ma) can be broadly characterized as follows (Cross-Chapter Box 2.1, Figure 1): (1) transient warming during the first 15 million years of the Cenozoic, punctuated by the Paleocene-Eocene Thermal Maximum; (2) a long-term cooling over tens of millions of years beginning around 50 Ma, driven by (among other factors) the slow drift of tectonic plates, which drove mountain building, erosion and volcanism, and reconfigured ocean passages, all of which ultimately moved carbon from the atmosphere to other reservoirs and led to the development of the Antarctic Ice Sheet (AIS) about 35–30 Ma; (2) the intensification of cooling by climate feedbacks involving interactions among tectonics, ice albedo, ocean circulation, land cover and greenhouse gases, causing ice sheets to develop in the Northern Hemisphere (NH) by about 3 Ma; (3) glacial-interglacial fluctuations paced by slow changes in Earth's astronomical configuration (orbital forcing) and modulated by changes in the global carbon cycle and ice sheets on time scales of tens to hundreds of thousands of years, with particular prominence during the last 1 Myr; (4) a transition with both gradual and abrupt shifts from the Last Glacial Maximum to the present interglacial epoch (Holocene), with sporadic ice-sheet breakup disrupting ocean circulation; (5) continued warming followed by minor cooling following the mid-Holocene, with superposed centennial- to decadal-scale fluctuations caused by volcanic activity, among other factors; (6) recent warming related to the build-up of anthropogenic greenhouse gases (Sections 2.2.3, 3.3.1).

GMST estimated for each of the reference periods based on proxy evidence (Section 2.3.1.1) can be compared with climate projections over coming centuries to place the range of possible futures into a longer-term context (Cross-Chapter Box 2.1, Figure 1). Here, the *very likely* range of GMST for the warmer world reference periods are compared with the *very likely* range of GSAT projected for the end the 21st century (2080–2100; Table 4.5 and the *likely* range for the end of the 23rd century (2300; Table 4.9) under multiple Shared Socioeconomic Pathway (SSP) scenarios. From this comparison, there is *medium confidence* in the following: GMST estimated for the warmest long-term period of the Last Interglacial about 125 ka (0.5–1.5°C relative to 1850–1900) overlaps with the low end of the range of temperatures projected under SSP1-2.6 including its negative emissions extension to the end of the 23rd century [1.0 to 2.2°C]. GMST estimated for a period of prolonged warmth during the mid-Pliocene Warm Period about 3 Ma [2.5 to 4.0°C] is similar to temperatures projected under SSP2-4.5 for the end of the 23rd century [2.3 to 4.6°C]. GMST estimated for the Miocene Climatic Optimum [5°C to 10°C] and Early Eocene Climatic Optimum [10 to 18°C], about 15 and 50 million years ago, respectively, overlap with the range projected for the end of the 23rd century under SSP5-8.5 [6.6 to 14.1°C].

[START CROSS-CHAPTER BOX 2.1, TABLE 1 HERE]

Cross-Chapter Box 2.1, Table 1: Paleo reference periods, listed from oldest to youngest. See 'AR6 sections' for literature citations related to each 'Sketch of the climate state.' See Working Group II (Chapters 1, 2, 3) for citations related to paleontological changes. See Interactive Atlas for simulated climate variables for MPWP, LIG, LGM and MH.

Period	**Age/ year***	**Sketch of the climate state (relative to 1850–1900), and *model experiment protocols*.** Values for large-scale climate indicators including global temperature, sea level and atmospheric CO_2 are shown in Figure 2.34.	**AR6 sections** partial list
Paleocene-Eocene thermal maximum (PETM)	55.9–55.7 Ma	A geologically rapid, large-magnitude warming event at the start of the Eocene when a large pulse of carbon was released to the ocean-atmosphere system, decreasing ocean pH and oxygen content. Terrestrial plant and animal communities changed composition, and species distributions shifted poleward. Many deep-sea species went extinct and tropical coral reefs diminished. *DeepMIP* (Lunt et al., 2017)	2.2.3.1 2.3.1.1.1 5.1.2.1 5.3.1.1 7.5.3.4
Early Eocene climatic optimum** (EECO)	53–49 Ma	Prolonged "hothouse" period with atmospheric CO_2 concentration >1000 ppm, similar to SSP5-8.5 end-of-century values. Continental positions were somewhat different to present due to tectonic plate movements; polar ice was absent and there was more warming at high latitudes than in the equatorial regions. Near-tropical forests grew at 70°S, despite seasonal polar darkness. *DeepMIP*, about 50 Ma (Lunt et al., 2017, 2021)	2.2.3.1 2.3.1.1.1 7.4.4.1.2 7.5.3.4 7.5.6
Miocene climatic optimum** (MCO)	16.9–14.7 Ma	Prolonged warm period with atmospheric CO_2 concentrations 400–600 ppm, similar to SSP2-4.5 end-of-century values. Continental geography was broadly similar to modern. At times, Arctic sea ice may have been absent, and the AIS was much smaller or perhaps absent. Peak in Cenozoic reef development. *MioMIP1*, Early and Middle Miocene (Steinthorsdottir et al., 2020)	2.2.3.1 2.3.1.1.1
Mid-Pliocene warm period (MPWP)	3.3–3.0 Ma	Warm period when atmospheric CO_2 concentration was similar to present (Cross-Chapter Box 2.4). The Arctic was much warmer, but tropical temperatures were only slightly warmer. Sea level was high. Treeline extended to the northern coastline of the NH continents. Also called, "Piacenzian warm period." *PMIP4 midPliocene-eoi400*, 3.2 Ma (Haywood et al., 2016; 2020)	CCB2.4 7.4.4.1.2 7.5.3.3 8.2.2.2 9.6.2
Last Interglacial (LIG)	129–116 ka	Most recent interglacial period, similar to mid-Holocene, but with more pronounced seasonal insolation cycle. Northern high latitudes were warmer, with reduced sea ice. Greenland and West Antarctic Ice Sheets were smaller and sea level was higher. Monsoon was enhanced. Boreal forests extended into Greenland and subtropical animals such as *Hippopotamus* occupied Britain. Coral reefs expanded latitudinally and contracted equatorially. *PMIP4 lig127k*, 127 ka (Otto-Bliesner, et al.,2017; 2021)	2.2.3.2 2.3.1.1.1 2.3.3.3 9.2.2.1 9.6.2
Last Glacial Maximum (LGM)	23–19 ka	Most recent glaciation when global temperatures were lower, with greater cooling toward the poles. Ice sheets covered much of North America and northwest Eurasia, and sea level was commensurately lower. Atmospheric CO_2 was lower; more carbon was sequestered in the ocean interior. Precipitation was generally lower over most regions; the atmosphere was dustier, and ranges of many plant species contracted into glacial refugia; forest extent and coral reef distribution was reduced worldwide. *PMIP4lgm*, 21 ka (Kageyama et al., 2017; 2021)	2.2.3.2 2.3.1.1.1 3.3.1.1 3.8.2.1 5.1.2.2 7.4.4.1.2 7.5.3.1 8.3.2.4 9.6.2
Last deglacial transition (LDT)	18–11 ka	Warming that followed the Last Glacial Maximum, with decreases in the extent of the cryosphere in both polar regions. Sea level, ocean meridional overturning circulation, and atmospheric CO_2 increased during two main steps. Temperate and boreal species ranges expanded northwards. Community turnover was large. Megafauna populations declined or went extinct.	2.2.3.2 5.1.2.2 5.3.1.2 8.6.1 9.6.2
Mid-Holocene (MH)	6.5–5.5 ka	Middle of the present interglacial when the CO_2 concentration was similar to the onset of the industrial era, but the orbital configuration led to warming and shifts in the hydrological cycle, especially NH monsoons. Approximate time during the current interglacial and before the onset of major industrial activities when GMST was highest. Biome-scale loss of North African grasslands caused by weakened monsoons and collapses of temperate tree populations linked to hydroclimate variability. *PMIP4 mid-Holocene*, 6 ka (Brierley et al., 2020; Otto-Bliesner et al., 2017)	2.3.1.1.2 2.3.2.4 2.3.3.3 3.3.1.1 3.8.2.1 8.3.2.4 8.6.2.2 9.6.2
Last millennium***	850-1850 CE	Climate variability during this period is better documented on annual to centennial scales than during previous reference periods. Climate changes were driven by solar, volcanic, land cover, and anthropogenic forcings, including strong increases in	2.3.1.1.2 2.3.2.3 8.3.1.6

		greenhouse gasses since 1750. *PMIP4 past1000,* 850–1849 CE (Jungclaus et al., 2017)	8.5.2.1 Box 11.3

* CE: Common Era; ka: thousands of years ago; Ma: millions of years ago.
** The word "optimum" is traditionally used in geosciences to refer to the warmest interval of a geologic period.
*** The terms "Little Ice Age" and "Medieval Warm Period" (or "Medieval Climate Anomaly") are not used extensively in this report because the timing of these episodes is not well defined and varies regionally. Since AR5, new proxy records have improved climate reconstructions at decadal scale across the last millennium. Therefore, the dates of events within these two roughly defined periods are stated explicitly when possible.

[END CROSS-CHAPTER BOX 2.1, TABLE 1 HERE]

[START CROSS-CHAPTER BOX 2.1, FIGURE 1 HERE]

Cross-Chapter Box 2.1, Figure 1: Global mean surface temperature (GMST) over the past 60 million years relative to 1850–1900 shown on three time scales. Information about each of the nine paleo reference periods (blue font) and sections in AR6 that discuss these periods are listed in Cross-Chapter Box 2.1 Table 1. Grey horizontal bars at the top mark important events. Characteristic uncertainties are based on expert judgement and are representative of the approximate midpoint of their respective time scales; uncertainties decrease forward in time. GMST estimates for most paleo reference periods (Figure 2.34) overlap with this reconstruction, but take into account multiple lines of evidence. Future projections span the range of global surface air temperature best estimates for SSP1–2.6 and SSP5–8.5 scenarios described in Section 1.6. Range shown for 2100 is based on CMIP6 multi-model mean for 2081–2100 from Table 4.5; range for 2300 is based upon an emulator and taken from Table 4.9. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END CROSS-CHAPTER BOX 2.1 HERE]

2.2 Changes in Climate Drivers

This section assesses the magnitude and rates of changes in both natural and anthropogenically mediated climate drivers over a range of time scales. First, changes in insolation (orbital and solar; 2.2.1), and volcanic stratospheric aerosol (2.2.2) are assessed. Next, well-mixed greenhouse gases (GHGs) (CO_2, N_2O and CH_4) are covered in 2.2.3, with climate feedbacks and other processes involved in the carbon cycle assessed in Chapter 5. The section continues with the assessment of changes in halogenated GHGs (2.2.4), stratospheric water vapour, stratospheric and tropospheric ozone (2.2.5), and tropospheric aerosols (2.2.6). Short-lived Climate Forcers (SLCFs), their precursor emissions and key processes are assessed in more detail in Chapter 6. Section 2.2.7 assesses the effect of historical land cover change on climate, including biophysical and biogeochemical processes. Section 2.2.8 summarizes the changes in the Earth's energy balance since 1750 using the comprehensive assessment of Effective Radiative Forcing (ERF) performed in Section 7.3. For some SLCFs with insufficient spatial or temporal observational coverage, ERFs are based on model estimates, but also reported here for completeness and context. Tabulated global mixing ratios of all well-mixed GHGs and ERFs from 1750–2019 are provided in Annex III.

2.2.1 Solar and Orbital Forcing

AR5 assessed solar variability over multiple time scales, concluding that total solar irradiance (TSI) multi-millennial fluctuations over the past 9 kyr were <1 W m^{-2}, but with no assessment of confidence provided. For multi-decadal to centennial variability over the last millennium, AR5 emphasized reconstructions of TSI that show little change (<0.1%) since the Maunder Minimum (1645–1715) when solar activity was particularly low, again without providing a confidence level. AR5 further concluded that the best estimate of radiative forcing due to TSI changes for the period 1750–2011 was 0.05–0.10 W m^{-2} (*medium confidence*),

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and that TSI *very likely* changed by –0.04 [–0.08–0.00 W m^{-2}] between 1986 and 2008. Potential solar influences on climate due to feedbacks arising from interactions with Galactic Cosmic Rays are assessed in Section 7.3.4.5.

Slow periodic changes in the Earth's orbit around the Sun mainly cause variations in seasonal and latitudinal receipt of incoming solar radiation. Precise calculations of orbital variations are available for tens of millions of years (Berger and Loutre, 1991; Laskar et al., 2011). The range of insolation averaged over boreal summer at 65°N was about 83 W m^{-2} during the past million years, and 3.2 W m^{-2} during the past millennium, but there was no substantial effect upon global average radiative forcing (0.02 W m^{-2} during the past millennium).

A new reconstruction of solar irradiance extends back 9 kyr based upon updated cosmogenic isotope datasets and improved models for production and deposition of cosmogenic nuclides (Poluianov et al., 2016), and shows that solar activity during the second half of the 20th century was in the upper decile of the range. TSI features millennial-scale changes with typical magnitudes of 1.5 [1.4 to 2.1] W m^{-2} (Wu et al., 2018). Although stronger variations in the deeper past cannot be ruled out completely (Egorova, T. et al., 2018; Reinhold et al., 2019), there is no indication of such changes having happened over the last 9 kyr.

Recent estimates of TSI and spectral solar irradiance (SSI) for the past millennium are based upon updated irradiance models (e.g., Egorova et al., 2018; Wu et al., 2018) and employ updated and revised direct sunspot observations over the last three centuries (Clette et al., 2014; Chatzistergos et al., 2017) as well as records of sunspot numbers reconstructed from cosmogenic isotope data prior to this (Usoskin et al., 2016). These reconstructed TSI timeseries (Figure 2.2a) feature little variation in TSI averaged over the past millennium. The TSI between the Maunder Minimum (1645–1715) and second half of the 20th century increased by 0.7–2.7 W m^{-2} (Jungclaus et al., 2017; Egorova et al., 2018; Lean, 2018; Wu, C.-J. et al., 2018; Yeo et al., 2020; Lockwood & Ball, 2020). This TSI increase implies a change in ERF of 0.09–0.35 W m^{-2} (Section 7.3.4.4).

Estimation of TSI changes since 1900 (Figure 2.2b) has further strengthened, and confirms a small (less than about 0.1 W m^{-2}) contribution to global climate forcing (Section 7.3.4.4). New reconstructions of TSI over the 20th century (Lean, 2018; Wu C-J. et al., 2018) support previous results that the TSI averaged over the solar cycle *very likely* increased during the first seven decades of the 20th century and decreased thereafter (Figure 2.2b). TSI did not change significantly between 1986 and 2019. Improved insights (Coddington et al., 2016; Yeo et al., 2015, 2017a; Krivova et al., 2006) show that variability in the 200–400 nm UV range was greater than previously assumed. Building on these results, the forcing proposed by Matthes et al. (2017) has a 16% stronger contribution to TSI variability in this wavelength range compared to the forcing used in the 5th Phase of the Coupled Model Intercomparison Project (CMIP5).

To conclude, solar activity since the late 19th century was relatively high but not exceptional in the context of the past 9 kyr (*high confidence*). The associated global-mean ERF is in the range of –0.06 to 0.08 W m^{-2} (Section 7.3.4.4).

[START FIGURE 2.2 HERE]

Figure 2.2: Time series of solar and volcanic forcing for the past 2.5 kyr (panels a, c) and since 1850 (panels b, d). (a) Total solar irradiance (TSI) reconstruction (10-year running averages) recommended for CMIP6 / PMIP4 millennial experiments based on the radiocarbon dataset before 1850 (blue) scaled to the CMIP6 historical forcing after 1850 (purple). (b) TSI time series (6-month running averages) from CMIP6 historical forcing as inferred from sunspot numbers (blue), compared to CMIP5 forcing based on (red) and an update to CMIP6 by a TSI composite (orange). (c) Volcanic forcing represented as reconstructed Stratospheric aerosol optical depth (SAOD; as presented in Section 7.3.4.6) at 550 nm. Estimates covering 500 BCE to 1900 CE (green) and 1850–2015 (blue). (d) SAOD reconstruction from CMIP6 (v 4) (blue), compared to CMIP5 forcing (red). Note the change in y-axis range between panels c and d. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.2 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.2.2 Volcanic Aerosol Forcing

AR5 concluded that, on inter-annual time scales, the radiative effects of volcanic aerosols are a dominant natural driver of climate variability, with the greatest effects occurring within the first 2–5 years following a strong eruption. Reconstructions of radiative forcing by volcanic aerosols used in the Paleoclimate Modelling Intercomparison Project Phase III (PMIP3) simulations and in AR5 featured short-lived perturbations of a range of magnitudes, with events of greater magnitude than –1 W m^{-2} (annual mean) occurring on average every 35–40 years, although no associated assessment of confidence was given. This section focuses on advances in reconstructions of stratospheric aerosol optical depth (SAOD), whereas Chapter 7 focuses on the effective radiative forcing of volcanic aerosols, and Chapter 5 assesses volcanic emissions of CO_2 and CH_4; tropospheric aerosols are discussed in Section 2.2.6. Cross-Chapter Box 4.1 undertakes an integrative assessment of volcanic effects including potential for 21st century effects.

Advances in analysis of sulphate records from the Greenland Ice Sheet (GrIS) and AIS have resulted in improved dating and completeness of SAOD reconstructions over the past 2.5 kyr (Sigl et al., 2015), a more uncertain extension back to 10 ka (Kobashi et al., 2017; Toohey and Sigl, 2017), and a better differentiation of sulphates that reach high latitudes via stratospheric (strong eruptions) versus tropospheric pathways (Burke et al., 2019; Gautier et al., 2019). The PMIP4 volcanic reconstruction extends the period analysed in AR5 by 1 kyr (Jungclaus et al., 2017; Figure 2.2c) and features multiple strong events that were previously misdated, underestimated or not detected, particularly before about 1500 CE. The period between successive large volcanic eruptions (Negative ERF greater than –1 W m^{-2}), ranges from 3–130 years, with an average of 43 ± 7.5 years between such eruptions over the past 2.5 kyr (data from Toohey & Sigl, 2017). The most recent such eruption was that of Mt Pinatubo in 1991. Century-long periods that lack such large eruptions occurred once every 400 years on average. Systematic uncertainties related to the scaling of sulphate abundance in glacier ice to radiative forcing have been estimated to be about 60% (Hegerl et al., 2006). Uncertainty in the timing of eruptions in the proxy record is ± 2 years (95% confidence interval) back to 1.5 ka and ± 4 years before (Toohey and Sigl, 2017).

SAOD averaged over the period 950–1250 CE (0.012) was lower than for the period 1450–1850 CE (0.017) and similar to the period 1850–1900 (0.011). Uncertainties associated with these inter-period differences are not well quantified but have little effect because the uncertainties are mainly systematic throughout the record. Over the past 100 years, SAOD averaged 14% lower than the mean of the previous 24 centuries (back to 2.5 ka), and well within the range of centennial-scale variability (Toohey and Sigl, 2017).

Direct observations of volcanic gas-phase sulphur emissions (mostly SO_2), sulphate aerosols, and their radiative effects are available from a variety of sources (Kremser et al., 2016). New estimates of SO_2 emissions from explosive eruptions have been derived from satellite (beginning in 1979) and in situ measurements (Höpfner et al., 2015; Carn et al., 2016; Neely and Schmidt, 2016; Brühl, 2018). Satellite observations of aerosol extinction after recent eruptions have uncertainties of about 15–25% (Vernier et al., 2011; Bourassa et al., 2012). Additional uncertainties occur when gaps in the satellite records are filled by complementary observations or using statistical methods (Thomason et al., 2018). Merged datasets (Thomason et al., 2018) and sparse ground-based measurements (Stothers, 1997) allow for volcanic forcing estimates back to 1850. In contrast to the CMIP5 historical volcanic forcing datasets (Ammann et al., 2003), updated time series (Luo et al., 2018; Figure 2.2d) feature a more comprehensive set of optical properties including latitude-, height- and wavelength-dependent aerosol extinction, single scattering albedo and asymmetry parameters. A series of small-to-moderate eruptions since 2000 resulted in perturbations in SAOD of 0.004–0.006 (Andersson et al., 2015; Schmidt et al., 2018).

To conclude, strong individual volcanic eruptions cause multi-annual variations in radiative forcing. However, the average magnitude and variability of SAOD and its associated volcanic aerosol forcing since 1900 are not unusual in the context of at least the past 2.5 kyr (*medium confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.2.3 Well-mixed Greenhouse Gases (WMGHGs)

Well-mixed greenhouse gases generally have lifetimes of more than several years. AR5 assigned *medium confidence* to the values of atmospheric CO_2 concentrations (mixing ratios) during the warm geological periods of the early Eocene and Pliocene. It concluded with *very high confidence* that, by 2011, the mixing ratios of CO_2, CH_4, and N_2O in the atmosphere exceeded the range derived from ice cores for the previous 800 kyr, and that the observed rates of increase of the greenhouse gases were unprecedented on centennial timescales over at least the past 22 kyr. It reported that over 2005–2011 atmospheric burdens of CO_2, CH_4, and N_2O increased, with 2011 levels of 390.5 ppm, 1803.2 ppb and 324.2 ppb, respectively. Increases of CO_2 and N_2O over 2005–2011 were comparable to those over 1996–2005, while CH_4 resumed increasing in 2007, after remaining nearly constant over 1999–2006. A comprehensive process-based assessment of changes in CO_2, CH_4, and N_2O is undertaken in Chapter 5.

2.2.3.1 CO_2 during 450 Ma to 800 ka

Isotopes from continental and marine sediments using improved analytical techniques and sampling resolution have reinforced the understanding of long-term changes in atmospheric CO_2 during the past 450 Myr (Table 2.1, Figure 2.3). In particular, for the last 60 Myr, sampling resolution and accuracy of the boron isotope proxy in ocean sediments has improved (Anagnostou et al., 2016; 2020; Babila et al., 2018; Chalk et al., 2017; de la Vega et al., 2020; Dyez et al., 2018; Gutjahr et al., 2017; Harper et al., 2020; Henehan et al., 2019; 2020; Penman et al., 2014; Raitzsch et al., 2018; Sosdian et al., 2018), the understanding of the alkenone CO_2 proxy has increased (e.g., Badger et al., 2019; Rae et al., 2021; Stoll et al., 2019; Zhang et al., 2019; 2020) and new phytoplankton proxies have been developed and applied (e.g. Witkowski et al., 2018). Understanding of the boron isotope CO_2 proxy has improved since AR5 with studies showing very good agreement between boron-CO_2 estimates and co-existing ice core CO_2 (Chalk et al., 2017; Foster, 2008; Henehan et al., 2013; Hönisch & Hemming, 2005; Raitzsch et al., 2018; Figure 2.3c). Such independent validation has proven difficult to achieve with the other available CO_2 proxies (e.g. Badger et al., 2019; Da et al., 2019; Stoll et al., 2019; Zhang et al., 2019). Remaining uncertainties in these ocean sediment based proxies (Hollis et al., 2019) partly limit the applicability of the alkenone $\delta^{13}C$ and boron $\delta^{11}B$ proxies beyond the Cenozoic, although new records are emerging, e.g. Jurikova et al., (2020). CO_2 estimates from the terrestrial CO_2 proxies, such as stomatal density in fossil plants and $\delta^{13}C$ of palaeosol carbonates, are available for much of the last 420 Myr. Given the low sampling density, relatively large CO_2 uncertainty, and high age uncertainty (relative to marine sediments) of the terrestrial proxies, preference here is given to the marine based proxies (and boron in particular) where possible.

Levels were close to 1750 values during at least one prolonged interval during the Carboniferous and Permian (350–252 Ma). During the Triassic (251.9–201.3 Ma), atmospheric CO_2 mixing ratios reached a maximum between 2000–5000 ppm (200–220 Ma). During the PETM (56 Ma) CO_2 rapidly rose from about 900 ppm to about 2000 ppm (Anagnostou et al., 2020; Gutjahr et al., 2017; Schubert & Jahren, 2013; Table 2.1) in 3–20 kyr (Gutjahr et al., 2017; Turner, 2018; Zeebe et al., 2016). Estimated multi-millennial rates of CO_2 accumulation during this event range from 0.3–1.5 PgC yr^{-1} (Gingerich, 2019); were at least 4-5 times lower than current centennial rates (Section 5.3.1.1). Based on boron and carbon isotope data, supported by other proxies (Hollis et al., 2019), atmospheric CO_2 during the EECO (50 Ma) was between 1150 and 2500 ppm (*medium confidence*), and then gradually declined over the last 50 Myr at a long-term rate of about 16 ppm Myr^{-1} (Figure 2.3). The last time the CO_2 mixing ratio was as high as 1000 ppm (the level reached by some high emission scenarios by 2100; Annex III) was prior to the Eocene-Oligocene transition (33.5 Ma; Figure 2.3) that was associated with the first major advance of the AIS (Anagnostou et al., 2016; Hollis et al., 2019; Pagani et al., 2011; Pearson et al., 2009; Witkowski et al., 2018). The compilation of Foster et al., (2017) constrained CO_2 concentration to between 290 and 450 ppm during the MPWP, based primarily on the boron-isotope data reported by Martínez-Botí et al. (2015b), consistent with the AR5 range of 300–450 ppm. A more recent high-resolution boron isotope-based study revealed that CO_2 cycled during the MPWP from about 330 to about 390 ppm on orbital timescales, with a mean of about 370 ppm (de la Vega et al., 2020). Although data from other proxy types (e.g., stomatal density or $\delta^{13}C$ of alkenones) have too low resolution to resolve the orbital variability of CO_2 during this interval (e.g. Kürschner et al., 1996; Stoll et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2019) there is general agreement among the different proxy types with the boron-derived mean (e.g. Stoll et al., 2019). High-resolution sampling (about 1 sample per 3 kyr) with the boron-isotope proxy indicates mean CO_2 mixing ratios for the Marine Isotope Stage KM5c interglacial were 360–420 ppm (*medium confidence*) (de la Vega et al., 2020).

Following the MPWP, the atmospheric CO_2 mixing ratio generally decreased at a rate of about 30 ppm Myr^{-1}. It is *very likely* that CO_2 levels as high as the present were not experienced in the last 2 Myr (Bartoli et al., 2011; Chalk et al., 2017; Da et al., 2019; Dyez et al., 2018; Hönisch et al., 2009; Martínez-Botí et al., 2015a; Stoll et al., 2019). Related to the shift of glacial-interglacial cycle frequency from 40 to 100 kyr at 0.8–1.2 Ma, there was a decrease of glacial-period CO_2 (Chalk et al., 2017; Dyez et al., 2018). These boron isotope-based CO_2 results agree with available records based on ancient ice exposed near the surface of the AIS (Yan et al., 2019), however, direct comparison is limited due to a lack of ancient ice cores with sufficiently continuous stratigraphy (Higgins et al., 2015; Brook and Buizert, 2018).

To conclude, there is *high confidence* that average EECO and MPWP (KM5c) CO_2 concentration was higher than those preceding industrialisation at 1150-2500 ppm and 360-420 ppm, respectively. Although there is some uncertainty due to the non-continuous nature of marine sediment records, the last time atmospheric CO_2 mixing ratio was as high as present was *very likely* more than 2 million years ago.

[START TABLE 2.1 HERE]

Table 2.1: Concentration (mixing ratios) and, where applicable, century time-scale rate of change of atmospheric CO_2 based on multiple datasets for target paleoclimate reference (Cross-Chapter Box 2.1, and Figure 2.34) and selected other periods. Modern data are from 2.2.3.3 and Annex III. 'AR6' denotes best estimates assessed in this report and propagated to Figure 2.34. Units for the rate of change are given only for centennial periods characterized by rapid changes. *Confidence* levels are *very high* for instrumentally derived concentrations, *high* for values derived from air in glacier ice (back to LIG), *medium* for values supported by multiple proxy types (MPWP, EECO), and *low* for values from a single sedimentary proxy type (PETM). '→' indicates transition from the beginning to the end of the time interval. Uncertainties for Modern are based on 2019 estimates. Last Millennium rate of range shows lowest and highest values attained during this period; LDT shows highest rate of change. See chapter data table for bibliographic citation and auxiliary information for each dataset (Table SM.1).

Reference period	**CO_2 concentration (ppm) and dataset details**	**Rate of change (ppm per century)**
Modern (1995-2014)	359.6 to 360.4 → 396.7 to 397.5 (AR6)	192.3 to 198.3* (AR6)
Last 100 years (1919-2019)	302.8 to 306.0 → 409.5 to 410.3 (AR6)	103.9 to 107.1 (AR6)
Approximate pre-industrial baseline (1850-1900) (See CCB1.2)	283.4 to 287.6 → 294.8 to 298.0 (AR6); 284.3† → 295.7† (CMIP6)	16.5 to 27.1* (AR6) 22.8†,* (CMIP6)
Last millennium (1000- 1750)	278.0 to 285.0 (AR6; average of WAIS Divide, Law Dome and EDML core data)	-6.9 ~ 4.7† (Law Dome); -1.9 ~ 3.2† (EDML); -5.2 ~ 4.2† (WAIS Divide)
MH	260.1 to 268.1 (Dome C; CMIP6)

[START FIGURE 2.3 HERE]

Figure 2.3: The evolution of atmospheric CO_2 through the last 450 million years. The periods covered are 0–450 Ma (a), 0–58 Ma (b), and 0–3500 ka (c), reconstructed from continental rock, marine sediment and ice core records. Note different timescales and axes ranges in panels (a), (b) and (c). Dark and light green bands in (a) are uncertainty envelopes at 68% and 95% uncertainty, respectively. 100 ppm in each panel is shown by the marker in the lower right hand corner to aid comparison between panels. In panel (b) and (c) the major paleoclimate reference periods (CCB2.1) have been labelled, and in addition: MPT (Mid Pleistocene Transition), MCO (Miocene Climatic Optimum). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.3 HERE]

2.2.3.2 Glacial-interglacial WMGHG Fluctuations from 800 ka

Since AR5, the number of ice cores for the last 800 kyr has increased and their temporal resolution has improved (Figure 2.4), especially for the last 60 kyr and when combined with analyses of firn air, leading to improved quantification of greenhouse gas concentrations prior to the mid-20th century.

2.2.3.2.1 CO_2

Records of CO_2 from the AIS formed during the last glacial period and the LDT show century-scale fluctuations of up to 9.6 ppm (Ahn et al., 2012; Ahn & Brook, 2014; Bauska et al., 2015; Marcott et al., 2014; Rubino et al., 2019). Although these rates are an order of magnitude lower than those directly observed over 1919–2019 CE (Section 2.2.3.3.1), they provide information on non-linear responses of climate-biogeochemical feedbacks (Section 5.1.2). Multiple records for 0–1850 CE show CO_2 mixing ratios of 274–285 ppm. Offsets among ice core records are about 1%, but the long-term trends agree well and show coherent multi-centennial variations of about 10 ppm (Ahn et al., 2012; Bauska et al., 2015; Rubino et al., 2019). Multiple records show CO_2 concentrations of 278.3 ± 2.9 ppm in 1750 and 285.5 ± 2.1 ppm in 1850 (Ahn et al., 2012, 2019; Bauska et al., 2015; MacFarling Meure et al., 2006; Siegenthaler et al., 2005). CO_2 concentration increased by 5.0 ± 0.8 ppm during 970–1130 CE, followed by a decrease of 4.6 ± 1.7 ppm during 1580–1700 CE. The greatest rate of change over the CE prior to 1750 is observed at about 1600 CE, and ranges from –6.9 to 4.7 ppm per century in multiple high-resolution ice core records (Ahn et al., 2012; Bauska et al., 2015; MacFarling Meure et al., 2006; Rubino et al., 2019; Siegenthaler et al., 2005). Although ice core records present low-pass filtered time series due to gas diffusion and gradual bubble close-off in the snow layer over the ice sheet (Fourteau et al., 2020), the rate of increase since 1850 CE (about 125 ppm

ACCEPTED VERSION SUBJECT TO FINAL EDITS

increase over about 170 years) is far greater than implied for any 170-year period by ice core records that cover the last 800 ka (*very high confidence*).

2.2.3.2.2 CH_4

CH_4 concentrations over the past 110 kyr are higher in the Northern Hemisphere (NH) than in the Southern Hemisphere (SH), but closely correlated on centennial and millennial timescales (WAIS Divide Project Members, 2015). On glacial to interglacial cycles, approximately 450 ppb oscillations in CH_4 concentrations have occurred (Loulergue et al., 2008). On millennial timescales, most rapid climate changes observed in Greenland and other regions are coincident with rapid CH_4 changes (Rhodes et al., 2015, 2017; WAIS Divide Project Members, 2015). The variability of CH_4 on centennial timescales during the early Holocene does not significantly differ from that of the late Holocene prior to about 1850 (Rhodes et al., 2013; Yang et al., 2017). The LGM concentration was 390.5 ± 6.0 ppb (Kageyama et al., 2017). The global mean concentrations during 0–1850 CE varied between 625 and 807 ppb. High-resolution ice core records from Antarctica and Greenland exhibit the same trends with an inter-polar difference of 36–47 ppb (Mitchell et al., 2013b; Sapart et al., 2012). There is a long-term positive trend of about 0.5 ppb per decade during the Common Era (CE) until 1750 CE. The most rapid CH_4 changes prior to industrialisation were as large as 30–50 ppb on multi-decadal timescales. Global mean CH_4 concentrations estimated from Antarctic and Greenland ice cores are 729.2 ± 9.4 ppb in 1750 and 807.6 ± 13.8 ppb in 1850 (Mitchell et al., 2013b).

2.2.3.2.3 N_2O

New records show that N_2O concentration changes are associated with glacial-interglacial transitions (Schilt et al., 2014). The most rapid change during the last glacial termination is a 30 ppb increase in a 200-year period, which is an order of magnitude smaller than the modern rate (Section 2.2.3.3). During the LGM, N_2O was 208.5 ± 7.7 ppb (Kageyama et al., 2017). Over the Holocene the lowest value was 257 ± 6.6 ppb during 6–8 ka, but millennial variation is not clearly detectable due to analytical uncertainty and insufficient ice core quality (Flückiger et al., 2002; Schilt et al., 2010). Recently acquired high-resolution records from Greenland and Antarctica for the last 2 kyr consistently show multi-centennial variations of about 5–10 ppb (Figure 2.4), although the magnitudes vary over time (Ryu et al., 2020). Three high temporal resolution records exhibit a short-term minimum at about 600 CE of 261 ± 4 ppb (MacFarling Meure et al., 2006; Ryu et al., 2020). It is *very likely* that industrial N_2O increase started before 1900 CE (Machida et al., 1995; Sowers, 2001; MacFarling Meure et al., 2006; Ryu et al., 2020). Multiple ice cores show N_2O concentrations of 270.1 ± 6.0 ppb in 1750 and 272.1 ± 5.7 ppb in 1850 (Flückiger et al., 1999; Machida et al., 1995; Rubino et al., 2019; Ryu et al., 2020; Sowers, 2001).

[START FIGURE 2.4 HERE]

Figure 2.4: Atmospheric WMGHG concentrations from ice cores. (a) Records during the last 800 kyr with the LGM to Holocene transition as inset. (b) Multiple high-resolution records over the CE. The horizontal black bars in the panel a inset indicate Last Glacial Maximum (LGM) and Last Deglacial Termination (LDT) respectively. The red and blue lines in (b) are 100-year running averages for CO_2 and N_2O concentrations, respectively. The numbers with vertical arrows in (b) are instrumentally measured concentrations in 2019. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.4 HERE]

2.2.3.3 Modern measurements of WMGHGs

In this section and for calculation of ERF, surface global averages are determined from measurements representative of the well-mixed lower troposphere. Global averages that include sites subject to significant anthropogenic activities or influenced by strong regional biospheric emissions are typically larger than those

ACCEPTED VERSION SUBJECT TO FINAL EDITS

from remote sites, and require weighting accordingly (Table 2.2). This section focusses on global mean mixing ratios estimated from networks with global spatial coverage, and updated from the CMIP6 historical dataset (Meinshausen et al., 2017) for periods prior to the existence of global networks.

[START TABLE 2.2 HERE]

Table 2.2: Atmospheric global annual mean mixing ratios (dry-air mole fraction) observed in 2011 and 2019, and relative changes since 2011, for selected well-mixed, radiatively important gases (ERF > 0.001 W m^{-2}), estimated from various measurement networks or compilations. Units are parts-per-million (ppm) for CO_2, parts-per-billion (ppb) for CH_4 and N_2O, parts-per-trillion (ppt) for all other gases. Time series since 1750, data for additional gases, references, and network information can be found in Annex III and the corresponding electronic supplement. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

AGAGE = Advanced Global Atmospheric Gases Experiment; SIO = Scripps Institution of Oceanography; NOAA = National Oceanic and Atmospheric Administration, Global Monitoring Laboratory; UCI = University of California, Irvine; CSIRO = Commonwealth Scientific and Industrial Research Organization, Aspendale, Australia; WMO = World Meteorological Organization, Global Atmosphere Watch, CMIP6 (Climate Model Intercomparison Project – Phase 6). Mixing ratios denoted by AR6 are representative of the remote, unpolluted troposphere, derived from one or more measurement networks (denoted by *). Minor differences between 2011 values reported here and in the previous Assessment Report (AR5) are due to updates in calibration and data processing. ERF in 2019 is taken from Table 7.5, and the difference with the AR5 assessment reflects updates in the estimates of AR6 global mixing ratios and updated radiative calculations. Uncertainties, in parenthesis, are estimated at 90% confidence interval. Networks use different methods to estimate uncertainties. Some uncertainties have been rounded up to be consistent with the number of decimal places shown. Lifetime is reported in years: # indicates multiple lifetimes for CO_2. For CH_4 and N_2O the two values represent total atmospheric lifetime and perturbation lifetime.

[END TABLE 2.2 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.2.3.3.1 Carbon Dioxide (CO_2)

There has been a positive trend in globally averaged surface CO_2 mixing ratios since 1958 (Figure 2.5a), that reflects the imbalance of sources and sinks (Section 5.2). The growth rate has increased overall since the 1960s (Figure 2.5a inset), while annual growth rates have varied substantially, e.g. reaching a peak during the strong El Niño events of 1997–1998 and 2015–2016 (Bastos et al., 2013; Betts et al., 2016). The average annual CO_2 increase from 2000 through 2011 was 2.0 ppm yr^{-1} (standard deviation 0.3 ppm yr^{-1}), similar to what was reported in AR5. From 2011 through 2019 it was 2.4 ppm yr^{-1} (standard deviation 0.5 ppm yr^{-1}), which is higher than that of any comparable time period since global measurements began. Global networks consistently show that the globally averaged annual mean CO_2 has increased by 5.0% since 2011, reaching 409.9 ± 0.4 ppm in 2019 (NOAA measurements). Further assessment of changing seasonality is undertaken in Section 2.3.4.1.

[START FIGURE 2.5 HERE]

Figure 2.5: Globally averaged dry-air mole fractions of well-mixed greenhouse gases. (a) CO_2 from SIO, CSIRO, and NOAA/GML (b) CH_4 from NOAA, AGAGE, CSIRO, and UCI; and (c) N_2O from NOAA, AGAGE, and CSIRO (see Table 2.2). Growth rates, calculated as the time derivative of the global means after removing seasonal cycle are shown as inset figures. Note that the CO_2 series is 1958–2019 whereas CH_4, and N_2O are 1979–2019. Further details on data are in Annex III, and on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.5 HERE]

2.2.3.3.2 Methane (CH_4)

The globally averaged surface mixing ratio of CH_4 in 2019 was 1866.3 ± 3.3 ppb, which is 3.5% higher than 2011, while observed increases from various networks range from 3.3–3.9% (Table 2.2; Figure 2.5b). There are marked growth rate changes over the period of direct observations, with a decreasing rate from the late-1970s through the late-1990s, very little change in concentrations from 1999–2006, and resumed increases since 2006. Atmospheric CH_4 fluctuations result from complex variations of sources and sinks. A detailed discussion of recent methane trends and our understanding of their causes is presented in Cross-Chapter Box 5.2.

2.2.3.3.3 Nitrous Oxide (N_2O)

AR5 reported 324.2 ± 0.1 ppb for global surface annual mean N_2O in 2011; since then, it has increased by 2.4% to 332.1 ± 0.4 ppb in 2019. Independent measurement networks agree well for both the global mean mixing ratio and relative change since 2011 (Table 2.2). Over 1995–2011, N_2O increased at an average rate of 0.79 ± 0.05 ppb yr^{-1}. The growth rate has been higher in recent years, amounting to 0.96 ± 0.05 ppb yr^{-1} from 2012 to 2019 (Figure 2.5c) (Section 5.2.3.5).

2.2.3.4 Summary of changes in WMGHGs

In summary, CO_2 has fluctuated by at least 2000 ppm over the last 450 Myr (*medium confidence*). The last time CO_2 concentrations were similar to the present-day was over 2 Ma (*high confidence*). Further, it is certain that WMGHG mixing ratios prior to industrialisation were lower than present-day levels and the growth rates of the WMGHGs from 1850 are unprecedented on centennial timescales in at least the last 800 kyr. During the glacial-interglacial climate cycles over the last 800 kyr, the concentration variations of the WMGHG were 50–100 ppm for CO_2, 210–430 ppb for CH_4 and 60–90 ppb for N_2O. Between 1750–2019 mixing ratios increased by 131.6 ± 2.9 ppm (47%), 1137 ± 10 ppb (156%), and 62 ± 6 ppb (23%), for CO_2, CH_4, and N_2O, respectively (*very high confidence*). Since 2011 (AR5) mixing ratios of CO_2, CH_4, and N_2O have further increased by 19 ppm, 63 ppb, and 7.7 ppb, reaching in 2019 levels of 409.9 (± 0.4) ppm, 1866.3 (± 3.3) ppb, and 332.1 (± 0.4) ppb, respectively. By 2019, the combined ERF (relative to 1750) of CO_2, CH_4 and N_2O was 2.9 ± 0.5 W m^{-2} (Table 2.2; Section 7.3.2).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.2.4 Halogenated Greenhouse Gases (CFCs, HCFCs, HFCs, PFCs, SF6 and others)

This category includes ozone depleting substances (ODS), their replacements, and gases used industrially or produced as by-products. Some have natural sources (Section 6.2.2.4). AR5 reported that atmospheric abundances of chlorofluorocarbons (CFCs) were decreasing in response to controls on production and consumption mandated by the Montreal Protocol on Substances that Deplete the Ozone Layer and its amendments. In contrast, abundances of both hydrochlorofluorocarbons (HCFCs, replacements for CFCs) and hydrofluorocarbons (HFCs, replacements for HCFCs) were increasing. Atmospheric abundances of perfluorocarbons (PFCs), SF_6, and NF_3 were also increasing.

Further details on ODS and other minor greenhouse gases can be found in the Scientific Assessment of Ozone Depletion: 2018 (Engel & Rigby, 2018; Montzka & Velders, 2018). Updated mixing ratios of the most radiatively important gases (ERF > 0.001 W m^{-2}) are reported in Table 2.2, and additional gases (ERF <0.001 W m^{-2}) are shown in Annex III.

2.2.4.1 CFCs

Atmospheric abundances of most CFCs have continued to decline since 2011 (AR5). The globally-averaged abundance of CFC-12 decreased by 25 ppt (4.8%) from 2011 to 2019, while CFC-11 decreased by about 11 ppt (4.7%) over the same period (Table 2.2, Figure 2.6). Atmospheric abundances of some minor CFCs (CFC-13, CFC-115, CFC-113a) have increased since 2011 (Annex III), possibly related to use of HFCs (Laube et al., 2014). Overall, as of 2019 the ERF from CFCs has declined by 9 ± 0.5% from its maximum in 2000, and 4.7 ± 0.6% since 2011 (Table 7.5).

While global reporting indicated that CFC-11 production had essentially ceased by 2010, and the atmospheric abundance of CFC-11 is still decreasing, emissions inferred from atmospheric observations began increasing in 2013–2014 and remained elevated for 5–6 years, suggesting renewed and unreported production (Montzka et al., 2018; 2021; Park et al., 2021; Rigby et al., 2019). The global lifetimes of several ozone-depleting substances have been updated (SPARC, 2013), in particular for CFC-11 from 45 to 52 years.

[START FIGURE 2.6 HERE]

Figure 2.6: Global mean atmospheric mixing ratios of select ozone-depleting substances and other greenhouse gases. Data shown are based on the CMIP6 historical dataset and data from NOAA and AGAGE global networks. PFCs include CF_4, C_2F_6, and C_3F_8, and *c*-C_4F_8; Halons include halon-1211, halon-1301, and halon-2402; other HFCs include HFC-23, HFC-32, HFC-125, HFC-143a, HFC-152a, HFC-227ea, HFC-236fa, HFC-245fa, and HFC-365mfc, and HFC-43-10mee. Note that the y-axis range is different for a, b and c and a 25 ppt yardstick is given next to each panel to aid interpretation. Further data are in Annex III, and details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.6 HERE]

2.2.4.2 HCFCs

The atmospheric abundances of the major HCFCs (HCFC-22, HCFC-141b, HCFC-142b), primarily used in refrigeration and foam blowing, are increasing, but rates of increase have slowed in recent years (Figure 2.6). Global mean mixing ratios (Table 2.2) showed good concordance at the time of AR5 for the period 2005–2011. For the period 2011–2019, the UCI network detected larger increases in HCFC-22, HCFC-141b, and HCFC-142b compared to the NOAA and AGAGE networks. Reasons for the discrepancy are presently unverified, but could be related to differences in sampling locations in the networks (Simpson et al., 2012). Emissions of HCFC-22, derived from atmospheric data, have remained relatively stable since 2012, while those of HCFC-141b and HCFC-142b have declined (Engel et al., 2018). Minor HCFCs, HCFC-133a and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

HCFC-31, have been detected in the atmosphere (currently less than 1 ppt) and may be unintentional by-products of HFC production (Engel et al., 2018).

2.2.4.3 HFCs, PFCs, SF6 and other radiatively important halogenated gases

Hydrofluorocarbons (HFCs) are replacements for CFCs and HCFCs. The atmospheric abundances of many HFCs increased between 2011 and 2019. HFC-134a (mobile air conditioning, foam blowing, and domestic refrigerators) increased by 71 % from 63 ppt in 2011 to 107.6 ppt in 2019 (Table 2.2). The UCI network detected a slightly smaller relative increase (53%). HFC-23, which is emitted as a by-product of HCFC-22 production, increased by 8.4 ppt (35%) over 2011–2019. HFC-32 used as a substitute for HCFC-22, increased at least by 300%, and HFC-143a and HFC-125 showed increases of 100% and 187%, respectively. While the ERF of HFC-245fa is currently < 0.001 W m^{-2}, its atmospheric abundance doubled since 2011 to 3.1 ppt in 2019 (Annex III). In contrast, HFC-152a is showing signs of stable (steady-state) abundance.

Other radiatively important gases with predominantly anthropogenic sources also continue to increase in abundance. SF_6, used in electrical distribution systems, magnesium production, and semi-conductor manufacturing, increased from 7.3 ppt in 2011 to 10.0 ppt in 2019 (+36%). Alternatives to SF_6 or SF_6-free equipment for electrical systems have become available in recent years, but SF_6 is still widely in use in electrical switch gear (Simmonds et al., 2020). The global lifetime of SF_6 has been revised from 3200 years to about 1000 years (Kovács et al., 2017; Ray et al., 2017) with implications for climate emission metrics (Section 7.6.2). NF_3, which is used in the semi-conductor industry, increased 147% over the same period to 2.05 ppt in 2019. Its contribution to ERF remains small, however, at 0.0004 W m^{-2}. The atmospheric abundance of SO_2F_2, which is used as a fumigant in place of ozone-depleting methyl bromide, reached 2.5 ppt in 2019, a 46% increase from 2011. Its ERF also remains small at 0.0005 W m^{-2}.

The global abundance of CCl_4 continues to decline, down about 9.6% since 2011. Following a revision of the global lifetime from 26 to 32 years, and discovery of previously unknown sources (e.g. biproduct industrial emissions), knowledge of the CCl_4 budget has improved. There is now better agreement between top-down emissions estimates (based on atmospheric measurements) and industry-based estimates (Engel et al., 2018). Halon-1211, mainly used for fire suppression, is also declining, and its ERF dropped below 0.001 W m^{-2} in 2019. While CH_2Cl_2 has a short atmospheric lifetime (6 months), and is not well-mixed, its abundance is increasing and its ERF is approaching 0.001 W m^{-2}.

Perfluorocarbons CF_4 and C_2F_6, which have exceedingly long global lifetimes, showed modest increases from 2011 to 2019. CF_4, which has both natural and anthropogenic sources, increased 8.2% to 85.5 ppt, and C_2F_6 increased 16.3% to 4.85 ppt. *c*-C_4F_8, which is used in the electronics industry and may also be generated during the production of polytetrafluoroethylene (PTFE, "Teflon") and other fluoropolymers (Mühle et al., 2019), has increased 34% since 2011 to 1.75 ppt, although its ERF remains below 0.001 W m^{-2}. Other PFCs, present at mixing ratios < 1 ppt, have also been quantified (Droste et al., 2020; Annex III).

2.2.4.4 Summary of changes in halogenated gases

In summary, by 2019 the ERF of halogenated GHGs has increased 3.5% since 2011, reflecting predominantly a decrease in the atmospheric mixing ratios of CFCs and an increase in their replacements. However, average annual ERF growth rates associated with halogenated gases since 2011 are a factor of seven lower than in the 1970s and 1980s. Direct radiative forcings from CFCs, HCFCs, HFCs, and other halogenated greenhouse gases were 0.28, 0.06, 0.04, and 0.03 W m^{-2} respectively, totalling 0.41 ± 0.07 W m^{-2} in 2019 (see Table 7.5).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.2.5 Other short-lived gases

2.2.5.1 Stratospheric water vapour

AR5 assessed *low confidence* in stratospheric water vapour (SWV) trends based on substantial seasonal and interannual variability in satellite data from 1992 to 2011. The 1980–2010 record of balloon-borne frost point hygrometer measurements over Boulder, Colorado (40°N), showed an average net increase of 1.0 ± 0.2 ppm (27 ± 6%) in the 16–26 km layer.

Since AR5, bias-adjusted spatially comprehensive SWV measurements by different satellite sensors were merged to form continuous records (Hegglin et al., 2014; Froidevaux et al., 2015; Davis et al., 2016). These indicate no net global increase of SWV in the lower stratosphere since the late 1980s. Hegglin et al. (2014) reported a latitudinal dependence of SWV trends and suggested that the upward trend over Boulder should not be considered representative of the global stratosphere, while Lossow et al. (2018) showed insignificant differences between SWV trends at Boulder and those for the 35–45°N zonal mean from 1980 to 2010 using model simulations and satellite observations.

Recent studies of dynamical influences on SWV (Eguchi et al., 2015; Evan et al., 2015; Tao et al., 2015; Konopka et al., 2016; Diallo et al., 2018; Garfinkel et al., 2018) have demonstrated that the quasi-biennial oscillation (QBO), El Niño-Southern Oscillation (ENSO), Sudden Stratospheric Warming (SSW) events and possibly also Pacific Decadal Variability (PDV) (Wang W. et al., 2016), can significantly influence SWV abundance and the tropical cold point tropopause temperatures that largely control water vapour entering the stratosphere. It has also been shown that the convective lofting of ice can moisten the lower stratosphere over large regions (Dessler et al., 2016; Anderson et al., 2017; Avery et al., 2017). Near-global observations of SWV have revealed unusually strong and abrupt interannual changes, especially in the tropical lower stratosphere. Between December 2015 and November 2016, the tropical mean SWV anomaly at 82 hPa dropped from 0.9 ± 0.1 ppm to –1.0 ± 0.1 ppm, accompanied by highly anomalous QBO-related dynamics in the tropical stratosphere (Newman P. et al., 2016; Tweedy et al., 2017) and the transition of ENSO from strong El Niño to La Niña conditions (Davis et al., 2017). The tropical mean SWV anomaly then rose sharply to 0.7 ± 0.1 ppm in June 2017 as warm westerlies returned to the tropical lower stratosphere and ENSO neutral conditions prevailed (Davis et al., 2017).

In summary, in situ measurements at a single mid-latitude location indicate about a 25% net increase in stratospheric water vapour since 1980, while merged satellite data records since the late 1980s suggest little net change. Recent studies of dynamical influences on SWV have highlighted their substantial roles in driving large interannual variability that complicates trend detection. There thus continues to be *low confidence* in trends of SWV over the instrumental period. Disregarding dynamic influences on SWV, an ERF of 0.05 ± 0.05 W m^{-2} is estimated for SWV produced by CH_4 oxidation (Section 7.3.2.6), unchanged from AR5.

2.2.5.2 Stratospheric ozone

AR5 assessed that it was certain that global stratospheric ozone from the mid-1990s to 2011 was nearly constant and about 3.5% lower than in the reference period 1964–1980. Most of the declines occurred prior to the mid-1990s.

Global annual mean total ozone (Figure 2.7) significantly declined by about 3.5% during the 1980s and the early 1990s and by 2.5% over 60°S–60°N (near-global). Then, during 2000–2017, both global and near-global concentrations increased slightly, but not significantly, all in line with production and consumption limits of ODS regulated under the Montreal Protocol and its amendments. Near-global 2014–2017 mean total ozone is about 2.2% below the pre-ozone depletion 1964–1980 average (Braesicke et al., 2018). At southern and northern mid-latitudes, declines are 5.5% and 3.0% compared to the 1964–1980 average respectively. Total ozone remained practically unchanged in the tropics (Braesicke et al., 2018). Emission of ODS started before 1980 and some estimates suggest that as much as 40% of the long-term ozone loss

ACCEPTED VERSION SUBJECT TO FINAL EDITS

occurred between 1960 and 1980 (Shepherd et al., 2014), lowering the 1964–1980 baseline values by about 1% (outside the polar regions), a value close to observational uncertainties. The world's longest record of total ozone measurements from Arosa, Switzerland, initiated in 1926, does not show any substantial long-term changes before about 1980 (Staehelin et al., 2018).

[START FIGURE 2.7 HERE]

Figure 2.7: Time series of annual mean total column ozone from 1964-2019. Values are in Dobson Units (DU), a good proxy for vertically integrated stratospheric ozone. Time series are shown for (a) near-global domain, (b-d) three zonal bands and (e) polar (60°–90°) total ozone in March (NH) and October (SH) ; the months when polar ozone losses usually are largest. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.7 HERE]

ERF depends strongly on the altitude of ozone changes. Two stratospheric regions are mainly responsible for long-term changes outside the polar regions. In the upper stratosphere (35–45 km), there was a strong decline (about 10%) from the start of observations in 1979 up to the mid-1990s and a subsequent increase by about 4% to present (SPARC/IO3C/GAW, 2019). In the lower stratosphere (20–25 km), there also was a statistically significant decline (7–8%) up to the mid-1990s, followed by stabilization or a small further decline (Ball et al., 2018; 2019), although the natural variability is too strong to make a conclusive statement (Chipperfield et al., 2018).

The strongest ozone loss in the stratosphere continues to occur in austral spring over Antarctica (ozone hole) with emergent signs of recovery after 2000 (Langematz et al., 2018). Interannual variability in polar stratospheric ozone is driven by large scale winds and temperatures, and, to a lesser extent, by the stratospheric aerosol loading and the solar cycle. This variability is particularly large in the Arctic, where the largest depletion events, comparable to a typical event in the Antarctic, occurred in 2011 (Manney et al., 2011; Langematz et al., 2018) and again in 2020 (Grooß and Müller, 2020; Manney et al., 2020). Further details on trends and ERF can be found in sections 6.3.2 and 7.3.2.5.

In summary, compared to the 1964–1980 average, stratospheric ozone columns outside polar regions (60°S–60°N) declined by about 2.5% over 1980–1995, and stabilized after 2000, with 2.2% lower values in 2014–2017. Large ozone depletions continue to appear in spring in the Antarctic and, in particularly cold years, also in the Arctic. Model based estimates disagree on the sign of the ERF due to stratospheric ozone changes, but agree that it is much smaller in magnitude than that due to tropospheric ozone changes (Section 7.3.2.5).

2.2.5.3 Tropospheric ozone

AR5 assessed *medium confidence* in large-scale increases of tropospheric ozone at rural surface sites across the NH (1970–2010), and in a doubling of European surface ozone during the 20th century, with the increases of surface ozone in the SH being of *low confidence*. Surface ozone *likely* increased in East Asia, but levelled off or decreased in the eastern USA and Western Europe. Free tropospheric trends (1971–2010) from ozonesondes and aircraft showed positive trends in most, but not all, assessed regions, and for most seasons and altitudes. This section focuses on large scale ozone changes; chemical and physical processes and regional changes in tropospheric ozone are assessed in Section 6.3.2.1 and Section 7.3.2.5 assesses radiative forcing.

Prior to 1850 ozone observations do not exist, but a recent analysis using clumped-isotope composition of molecular oxygen ($^{18}O^{18}O$ in O_2) trapped in polar firn and ice, combined with atmospheric chemistry model simulations, constrains the global tropospheric ozone increase to less than 40% between 1850 and 2005, with most of this increase occurring between 1950 and 1980 (Yeung et al., 2019). Recently, the Tropospheric Ozone Assessment Report identified and evaluated 60 records of surface ozone observations collected at

ACCEPTED VERSION SUBJECT TO FINAL EDITS

rural locations worldwide between 1896 and 1975, which were based on a range of measurement techniques with potentially large uncertainties (Tarasick et al., 2019). They found that from the mid-20th century (1930s to the early 1970s) to 1990–2014, rural surface ozone increased by 30–70% across the northern extra-tropics. This is smaller than the 100% 20th century increase reported in AR5, which relied on far fewer measurement sites, all in Europe. In the northern tropics limited low-elevation historical data (1954–1975) provide no clear indication of surface ozone increases (Tarasick et al., 2019). However, similar to the northern mid-latitude increases, lower-free tropospheric ozone at Mauna Loa, Hawaii increased by approximately 50% from the late 1950s to present (Cooper et al., 2020). Historical observations are too limited to draw conclusions on surface ozone trends in the SH tropics and mid-latitudes since the mid-20th century, with tropospheric ozone exhibiting little change across Antarctica (Tarasick et al., 2019; Cooper et al., 2020). Based on reliable UV absorption measurements at remote locations (surface and lower troposphere), ozone trends since the mid-1990s varied spatially at northern mid-latitudes, but increased in the northern tropics (2-17%; 1-6 ppbv per decade) (Cooper et al., 2020; Gaudel et al., 2020). Across the SH these more recent observations are too limited to determine zonal trends (e.g. tropics, mid-latitudes, high latitudes).

The earliest observations of free tropospheric ozone (1934–1955) are available from northern mid-latitudes where limited data indicate a tropospheric column ozone increase of 48 ± 30% up to 1990–2012 (Tarasick et al., 2019). Starting in the 1960s, records from ozonesondes show no significant changes in the free troposphere over the Arctic and mid-latitude regions of Canada, but trends are mainly positive elsewhere in the northern mid-latitudes (Cooper et al., 2020; Oltmans et al., 2013). Tropospheric column and free tropospheric trends since the mid-1990s based on commercial aircraft, ozonesonde observations and satellite retrievals (Figure 2.8b,c), are overwhelmingly positive across the northern mid-latitudes (2–7%; 1–4 ppbv per decade) and tropics (2–14%; 1–5 ppbv per decade), with the largest increases (8–14%; 3–6 ppbv per decade) in the northern tropics in the vicinity of southern Asia and Indonesia. Observations in the SH are limited, but indicate average tropospheric column ozone increases of 2–12% (1–5 ppbv) per decade in the tropics (Figure 2.8c), and weak tropospheric column ozone increases (< 5%, < 1 ppbv per decade) at mid-latitudes (Cooper et al., 2020). Above Antarctica, mid-tropospheric ozone has increased since the late 20th century (Oltmans et al., 2013). The total ozone ERF from 1750 to 2019 best estimate is assessed as 0.47 W m^{-2} (7.3.2.5) and this is dominated by increases in the troposphere. The underlying modelled global tropospheric ozone column increase (Skeie et al., 2020) from 1850 to 2010 of 40–60%, is somewhat higher than the isotope based upper-limit of Yeung et al., (2019). At mid-latitudes (30°–60° N) model increases of 30–40% since the mid-20th century are broadly consistent with observations.

In summary, *limited* available isotopic *evidence* constrains the global tropospheric ozone increase to less than 40% between 1850 and 2005 (*low confidence*). Based on sparse historical surface/low altitude data tropospheric ozone has increased since the mid-20th century by 30–70% across the NH (*medium confidence*). Surface / low altitude ozone trends since the mid-1990s are variable at northern mid-latitudes, but positive in the tropics [2 to 17% per decade] (*high confidence*). Since the mid-1990s, free tropospheric ozone has increased by 2–7% per decade in most regions of the northern mid-latitudes, and 2–12% per decade in the sampled regions of the northern and southern tropics (*high confidence*). Limited coverage by surface observations precludes identification of zonal trends in the SH, while observations of tropospheric column ozone indicate increases of less than 5% per decade at southern mid-latitudes (*medium confidence*).

[START FIGURE 2.8 HERE]

Figure 2.8: Surface and tropospheric ozone trends. (a) Decadal ozone trends by latitude at 28 remote surface sites and in the lower free troposphere (650 hPa, about 3.5 km) as measured by IAGOS aircraft above 11 regions. All trends are estimated for the time series up to the most recently available year, but begin in 1995 or 1994. Colours indicate significance (p-value) as denoted in the in-line key. See Figure 6.5 for a depiction of these trends globally. (b) Trends of ozone since 1994 as measured by IAGOS aircraft in 11 regions in the mid-troposphere (700–300 hPa; about 3–9 km) and upper troposphere (about 10-12 km), as measured by IAGOS aircraft and ozonesondes. (c) Trends of average tropospheric column ozone mixing ratios from the TOST composite ozonesonde product and three composite satellite products based on TOMS, OMI/MLS (Sat1), GOME, SCIAMACHY, OMI, GOME-2A, GOME-2B (Sat2), and GOME, SCIAMACHY, GOME-II (Sat3). Vertical bars indicate the latitude range of each product, while horizontal lines indicate the *very likely* uncertainty range.. Further details on data sources and processing

ACCEPTED VERSION SUBJECT TO FINAL EDITS

are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.8 HERE]

2.2.6 Aerosols

AR5 assessed large-scale Aerosol Optical Depth (AOD) trends over 2000–2009, concluding that there was *low confidence* in a global trend, but that AOD *very likely* decreased from 1990 onwards over Europe and the eastern USA, and increased since 2000 over eastern and southern Asia. The ERF associated with aerosol-radiation interactions for 2011 (relative to 1750) was estimated to be -0.45 ± 0.5 W m^{-2} and of aerosol-cloud interaction estimated as -0.45 [-1.2–0.0] W m^{-2}. Aerosol ERF uncertainty was assessed as the largest contributor to the overall ERF uncertainty since 1750.

This section assesses the observed large-scale temporal evolution of tropospheric aerosols. Aerosol-related processes, chemical and physical properties, and links to air quality, are assessed in Chapter 6. An in-depth assessment of aerosol interactions with radiation and clouds is provided in Section 7.3.3.

Aerosol proxy records of improved temporal resolution and quality are now available (Dornelas et al., 2018; Jacobel et al., 2017; Kylander et al., 2016; Middleton et al., 2018; Stevens et al., 2016; 2018), which further advance synthesis of new global compilations of aerosol loadings (Lambert et al., 2015; Albani et al., 2016). Estimates of the glacial / interglacial ratio in global dust deposition are within the range of 2–4 (Albani et al., 2015; Lambert et al., 2015). New reconstructions indicate a ratio of 3–5 for the glacial / interglacial loadings for mid- and high-latitude ocean of both hemispheres (Lamy et al., 2014; Martinez-Garcia et al., 2014; Serno et al., 2015). Improved quantification of changes in dust deposition from North Africa and North Atlantic sediment records confirms dust deposition rates lower by a factor 2–5 during the African Humid Period (10–5 ka) compared to the late Holocene (McGee et al., 2013; Albani et al., 2015; Middleton et al., 2018; Palchan & Torfstein, 2019). During the Holocene, biogenic emissions and volcanic activity drove significant variability (up to one order of magnitude) in sulphate concentrations (Schüpbach et al., 2018).

Ice cores allow for estimation of multi-centennial trends in mid- and high-latitude aerosol deposition, including those for sulphate and black carbon (Figure 2.9 a, b). Sulphate in ice cores increased by a factor of 8 from the end of the 19th century to the 1970s in continental Europe, by a factor of 4 from the 1940s to the 1970s in Russia, and by a factor of 3 from the end of the 19th century to 1950 in the Arctic (Svalbard). In all regions studied, concentrations have declined by about a factor of 2 following their peak (around 1970 in Europe and Russia, and 1950 in the Arctic). Strong increases of black carbon (BC) were observed in the 20th century over Europe, Russia, Greenland (primarily originating from emissions from North America), and in the Arctic (Svalbard). South America exhibits a small positive trend (Figure 2.9). BC concentrations in various Antarctic ice cores were below 1 ng g^{-1} without a clear trend.

Spatially resolved trends of AOD derived from Aqua/Terra MISR and MODIS instruments over 2000–2019 range between -2% and 2% per year (Figure 2.9c). Ground-based solar attenuation networks help to constrain and improve the satellite-derived retrievals of AOD, and trends derived from the AERONET network (Figure 2.9c, d) corroborate satellite results (Bauer et al., 2020; Georgoulias et al., 2016; Wei et al., 2019; Yu et al., 2020) in particular for declines over Europe (Stjern et al., 2011; Cherian et al., 2014; Li et al., 2014) and the USA (Jongeward et al., 2016; Li et al., 2014). The tendency in AOD over East Asia reversed from positive (2000–2010) to negative (since 2010) (Filonchyk et al., 2019; Ma et al., 2019; Samset et al., 2019; Sogacheva et al., 2018). Over southern Asia, however, AOD from satellite (MODIS / MISR) and AERONET retrievals show continuing increases (Li et al., 2014; Zhao et al., 2017), with similar trends from UV-based aerosol retrievals from the Ozone Monitoring Instrument (OMI) on the Aura satellite (Dahutia et al., 2018; Hammer et al., 2018). A comparison of MODIS and MISR radiometric observations with the broadband CERES satellite instrument (Corbett and Loeb, 2015) showed that drifts in calibration are *unlikely* to affect the satellite derived trends. CERES shows patterns for clear-sky broadband radiation consistent with the aerosol spatio-temporal changes (Loeb et al., 2018; Paulot et al., 2018).

Satellite-derived trends are further supported by in situ regional surface concentration measurements,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

operational since the 1980s (sulphate) and 1990s (PM2.5) from a global compilation (Coen et al., 2020) of networks over Europe (Stjern et al., 2011), North America (Jongeward et al., 2016), and China (Zheng et al., 2018). Collaud Coen et al. (2020) report from surface observations across the NH mid-latitudes that aerosol absorption coefficients decreased since the first decade of the 21st century.

Anthropogenic aerosol is predominantly found in the fraction of particles with radii <1 μm that comprise the fine-mode AOD (AODf) (Kinne, 2019) (Figure 2.9d). A significant decline in AODf of more than 1.5% per year from 2000 to 2019 has occurred over Europe and North America, while there have been positive trends of up to 1.5% per year over Southern Asia and East Africa. The global-scale trend in AODf of –0.03% per year (Figure 2.9) is significant. The results are consistent with trend estimates from an aerosol reanalysis (Bellouin et al., 2020), and the trends in satellite-derived cloud droplet number concentrations are consistent with the aerosol trends (Cherian and Quaas, 2020). Cloudiness and cloud radiative properties trends are, however, less conclusive possibly due to their large variability (Norris et al., 2016; Cherian and Quaas, 2020). Further details on aerosol-cloud interactions are assessed in Section 7.3.3.2.

[START FIGURE 2.9 HERE]

Figure 2.9: Aerosol evolution from ice-core measurements. Changes are shown as 10-yr averaged time series (a, b) and trends in remote-sensing aerosol optical depth (AOD) and AODf (c, d). (a) Concentrations of non-sea salt (nss) sulphate (ng g^{-1}). (b) Black carbon (BC) in glacier ice from the Arctic (Lomonosovfonna), Russia (Belukha), Europe (Colle Gnifetti), South America (Illimani), Antarctica (stacked sulphate record, and BC from the B40 core), and BC from Greenland (stacked rBC record from Greenland and Eastern Europe (Elbrus)). (c) Linear trend in annual mean AOD retrieved from satellite data for the 2000–2019 period (% yr^{-1}). The average trend from MODerate Resolution Imaging Spectroradiometer (MODIS) and Multi-Angle Imaging Spectroradiometer (MISR) is shown. Trends are calculated using OLS regression with significance assessed following AR(1) adjustment after Santer et al., (2008a). Superimposed are the trends in annual-mean AOD from the AERONET surface sunphotometer network for 2000–2019. (d) Linear trend in 2000–2019 as in (c), but for fine-mode AOD, AODf, and using only MISR over land. Significance is assessed following AR(1) adjustment after Santer et al., (2008a), 'x' marks denote non-significant trends. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.9 HERE]

To conclude, atmospheric aerosols sampled by ice cores, influenced by northern mid-latitude emissions, show positive trends from 1700 until the last quarter of the 20th century and decreases thereafter (*high confidence)*, but there is *low confidence* in observations of systematic changes in other parts of the world in these periods. Satellite data and ground-based records indicate that AOD exhibits predominantly negative trends since 2000 over NH mid-latitudes and SH continents, but increased over South Asia and East Africa (*high confidence*). A globally deceasing aerosol abundance is thus assessed with *medium confidence*. This implies increasing net positive ERF, since the overall negative aerosol ERF has become smaller.

2.2.7 Land use and land cover

AR5 assessed that land use change *very likely* increased the Earth's albedo with a radiative forcing of -0.15 (± 0.10) W m^{-2}. AR5 also assessed that a net cooling of the surface, accounting for processes that are not limited to the albedo, was *about as likely as not*. SRCCL concluded with *medium confidence* that the biophysical effects of land cover change (mainly increased albedo) had a cooling effect on surface temperatures. SRCCL also concluded with *very high confidence* that the biogeochemical effects of land cover change (i.e., GHG emissions) resulted in a mean annual surface warming.

Much of the global land surface has been modified or managed to some extent by human activities during the Holocene. Reconstructions based on pollen data indicate that natural vegetation probably covered most of

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the Earth's ice-free terrestrial surface until roughly the mid-Holocene (Harrison et al., 2020; Li et al., 2020; Marquer et al., 2017). Reconstructions based on pollen, archaeological, and historical data indicate deforestation at the regional scale since at least 6 ka (Harrison et al., 2020; Li et al., 2020; Marquer et al., 2017; Stephens et al., 2019). From a global perspective, land-use forcing datasets (Lawrence et al., 2016) estimate that changes in land use (and related deforestation) were small on the global scale until the mid-19th century and accelerated markedly thereafter, with larger uncertainties prior to industrialization (Kaplan et al., 2017). Since the early 1980s, about 60% of all land cover changes have been associated with direct human activities, with spatial patterns emphasizing the regional character of land use and land management, including tropical deforestation, temperate afforestation, cropland intensification, and increased urbanization (Song et al., 2018, Zeng et al., 2018). At present, nearly three-quarters of the ice-free terrestrial surface is under some form of human use (Venter et al., 2016; Erb et al., 2017), particularly in agriculture and forest management.

The impact of historical land-cover change on global climate is assessed with model simulations that consider multiple climate and biophysical processes (e.g., changes in albedo, evapotranspiration, and roughness) and / or biogeochemical processes (e.g., changes in atmospheric composition such as carbon release from deforestation). The dominant biophysical response to land cover changes is albedo, which is estimated (using a MODIS albedo product and a historical land-use harmonization product) to have increased gradually prior to the mid-19th century and then strongly through the mid-20th century, with a slightly slower rise thereafter (Ghimire et al., 2014). Recent radiative forcing estimates arising from biophysical processes generally fall at the lower end of the AR5 assessed range. For instance, based on historical simulations from 13 CMIP6 models, Smith et al., (2020) estimated that the ERF from surface albedo changes (including snow cover and leaf area) was -0.08 [-0.22 to 0.06] W m^{-2} since 1850. Similarly, based on simulations from 13 CMIP5 models, Lejeune et al., (2020) estimated the radiative forcing from transitions between trees, crops, and grasslands was -0.11 [-0.16 to 0.04] W m^{-2} since 1860. Andrews et al., (2017) identified an ERF of -0.40 W m^{-2} since 1860, ascribing much of the effect to increases in albedo (including the unmasking of underlying snow cover); notably, however, the analysis was based on a single model with a known tendency to overestimate the ERF (Collins et al., 2011). Ward et al. (2014) examined the combined effects of biophysical and biogeochemical processes, obtaining an RF of 0.9 ± 0.5 W m^{-2} since 1850 that was driven primarily by increases in land-use related GHG emissions from deforestation and agriculture (Ward and Mahowald, 2015). According to a large suite of historical simulations, the biophysical effects of changes in land cover (i.e. increased surface albedo and decreased turbulent heat fluxes) led to a net global cooling of 0.10 ± 0.14 °C at the surface (SRCCL). Available model simulations suggest that biophysical and biogeochemical effects jointly may have contributed to a small global warming of 0.078 ± 0.093 ℃ at the surface over about the past two centuries (SRCCL), with a potentially even larger warming contribution over the Holocene as a whole (He et al., 2014).

In summary, biophysical effects from historical changes in land use have an overall negative ERF (*medium confidence*). The best-estimate ERF from the increase in global albedo is -0.15 W m^{-2} since 1700 and -0.12 W m^{-2} since 1850 (*medium confidence*; Section 7.3.4.1). Biophysical effects of land-use change *likely* resulted in a net global cooling of about 0.1°C since 1750 (*medium confidence*; Section 7.3.5.3).

2.2.8 Effective radiative forcing (ERF) exerted by the assessed climate drivers

AR5 concluded that changes in climate drivers over the industrial period corresponded to a positive ERF which increased more rapidly after 1970 than before. There was *very high confidence* in the positive ERF due to WMGHG, with CO_2 the single largest contributor. AR5 concluded that there was *high confidence* that aerosols have offset a substantial portion of the WMGHG forcing.

This section reports the evolution in ERF with respect to 1750 as assessed in Section 7.3 and relies on the observed changes in climate drivers as assessed in Section 2.2 wherever possible, and models otherwise. The ERF is assessed using the methods and details described in Section 7.3.1 and includes, in addition to the radiative forcing, the rapid adjustments, especially implied by clouds. The time series are shown in Figure 2.10.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Increasing TSI (Section 2.2.1) implies a small ERF of less than 0.1 W m^{-2} between 1900 and 1980. TSI varies over the 11-year solar cycle with ERF of order ± 0.1 W m^{-2} in the assessed period. Strong volcanic eruptions (Section 2.2.2) with periods of strong negative ERF lasting 2–5 years in duration occurred in the late 19th and early 20th centuries. There followed a relatively quiescent period between about 1920 and 1960, and then three strong eruptions in 1963, 1982 and 1991, and only small-to-moderate eruptions thereafter (Schmidt et al., 2018).

The atmospheric concentrations of WMGHGs (Section 2.2.3) have continuously increased since the early 19th century, with CO_2 contributing the largest share of the positive ERF. Compared to the last two decades of the 20th century, the growth rate of CO_2 in the atmosphere increased in the 21st century, showed strong fluctuations for CH_4, and was about constant for N_2O. Mixing ratios of the most abundant CFCs declined (Section 2.2.4). Mixing ratios of HCFCs increased, but growth rates are starting to decelerate. Mixing ratios of HFCs and some other human-made components are increasing (Section 2.2.4). The ERF for CO_2 alone is stronger than for all the other anthropogenic WMGHGs taken together throughout the industrial period, and its relative importance has increased in recent years (Figures 2.10, 7.6).

[START FIGURE 2.10 HERE]

Figure 2.10: Temporal evolution of effective radiative forcing (ERF) related to the drivers assessed in Section 2.2. ERFs are based upon the calculations described in Chapter 7, of which the global annual mean, central assessment values are shown as lines and the 5 to 95% uncertainty range as shading (Section 7.3, see Figures 7.6 to 7.8 for more detail on uncertainties). The inset plot shows the rate of change (linear trend) in total anthropogenic ERF (total without TSI and volcanic ERF) for 30-year periods centred at each dot. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.10 HERE]

Among the gaseous short-lived climate forcers (Section 2.2.5, Chapter 6, Section 7.3; excluding CH_4 here), ozone (O_3) is the component with the largest (positive) ERF. Concentrations from direct observations have increased since the mid-20th century and, mostly based on models, this extends to since 1750. Other gaseous short-lived climate forcers have small contributions to total ERF.

The net effect of aerosols (Sections 2.2.6, 6.4) on the radiation budget, including their effect on clouds, and cloud adjustments, as well as the deposition of black carbon on snow (Section 7.3.4.3), was negative throughout the industrial period (*high confidence*). The net effect strengthened (becoming more negative) over most of the 20th century, but *more likely than not* weakened (becoming less negative) since the late 20th century. These trends are reflected in measurements of surface solar radiation (Section 7.2.2.3) and the Earth's energy imbalance (Section 7.2.2.1). The relative importance of aerosol forcing compared to other forcing agents has decreased globally in the most recent 30 years (*medium confidence*) and the reduction of the negative forcing in the 21st century enhances the overall positive ERF.

Land use and land cover changes (Section 2.2.7) over the industrial period introduce a negative radiative forcing by increasing the surface albedo. This effect increased since 1750, reaching current values of about –0.20 W m^{-2} (*medium confidence*). This ERF value is taken from Section 7.3.4.1 and is different from the assessment in Section 2.2.7 in that it also includes the effect of irrigation. It also includes uncertain rapid adjustments and thus there is *low confidence* in its magnitude. Biogeochemical feedbacks can be substantial (Section 5.4) and are not included in ERF.

In conclusion, the net ERF due to all observed changes in climate drivers is positive, except for short periods (up to a few years in duration) following moderate to large volcanic eruptions, and has grown in magnitude since the late 19th century. The rate of change *likely* has increased in the last 30 years, since CO_2 concentrations increased at an increasing rate due to growing CO_2 emissions (*very likely*), and since the aerosol forcing became less negative (*more likely than not*).

2.3 Changes in large-scale climate

[START CROSS-CHAPTER BOX 2.2 HERE]

Cross-Chapter Box 2.2: Large-scale indicators of climate change

Contributing Authors: Veronika Eyring (Germany), Nathan Gillett (Canada), Sergey Gulev (Russian Federation), Jochem Marotzke (Germany), June-Yi Lee (Republic of Korea), Peter Thorne (Ireland/UK)

Chapters 2, 3 and 4 assess the current evidence basis for climatic changes, their causes, and their potential future under different possible emissions pathways using a combination of observations and state-of-the-art Earth System Models (ESMs). The assessment in these chapters focuses on selected large-scale indicators and modes as defined in this Box. These indicators and modes of variability taken together characterise overall changes to the climate system as a whole.

Defining large-scale

Understanding of large-scale climate variability and change requires knowledge of both the response to forcings and the role of internal variability. Many forcings have substantial hemispheric or continental scale variations. Modes of climate variability are generally driven by ocean basin scale processes. The climate system involves process interactions from the micro- to the global-scale and as such, any threshold for defining "large-scale" is arbitrary, but, within these chapters on the basis of these considerations large-scale is defined to include ocean basin and continental scales as well as hemispheric and global scales.

Defining a key set of climate indicators

Key climate indicators should constitute a finite set of distinct variables and / or metrics that may collectively point to important overall changes in the climate system that provide a synthesis of climate system evolution and are of broad societal relevance. Key indicators have been selected across the atmospheric, oceanic, cryospheric and biospheric domains, with land as a cross-cutting component. These indicators, and their use across chapters 2 to 4, as well as the broader report, are summarized in Cross-Chapter Box 2.2 Table 1. All selected indicators are Essential Climate Variables as defined by the Global Climate Observing System (Bojinski et al., 2014).

[START CROSS-CHAPTER BOX 2.2, TABLE 1 HERE]

Cross-Chapter Box 2.2, Table 1: Summary of the large-scale indicators used across chapters 2 through 4 and their principal applications in remaining chapters. Indicators are sub-divided by Earth-system domain and their inclusion in individual chapters is indicated by an orange solid fill. The list of additional chapters is limited to those where the variable is a principal consideration.

Atmospheric indicators

Monitoring surface temperatures is integral to the negotiations of UNFCCC and the global mean temperature goals of the Paris Agreement. Upper-air temperatures are a key indicator of different causal mechanisms underlying climate change and underpinned the very first conclusion in the Second Assessment Report of a 'discernible human influence' (Santer et al., 1996). To ascertain large-scale changes of and human influence on the global hydrological cycle (which includes terrestrial and oceanic components), a small subset of indicators across this cycle are chosen: ocean and land precipitaion-evaproation (P-E), global precipitation, total column water vapour, surface humidity (specific and relative), and global river runoff. Chapter 8 performs a substantive and holistic assessment of a much broader range of components. Finally, a warming world may be accompanied by a change in large-scale circulation patterns linked through energy / mass / momentum constraints such as the extent and strength of the Hadley circulation (HC), monsoon systems, and / or the position and strength of the sub-tropical and polar jets.

Cryospheric indicators

Changes in ice sheets are indicators of the longest-term impacts of climate change and associated with changes in global and regional sea level. Seasonal snow cover has many implications for mid- to high-latitude regions (albedo, hydrological cycle, etc.) with impacts on biospheric components of the system. Changes in sea ice extent, seasonality and thickness have potential impacts for hemispheric-scale circulation (Cross-Chapter Box 10.1). Changes in glacier mass balance contribute to changes in sea level but also have substantial implications for water supply for a substantial proportion of the global population. Finally, changes in permafrost and the seasonally thawed active layer have substantial implications in mid- to high-latitudes and have been hypothesised to be important in potential feedbacks through degassing of WMGHGs as the permafrost thaws.

Oceanic indicators

Most of the energy imbalance (Box 7.2) in the climate system is taken up by the ocean, resulting in changes in ocean temperature and heat content. Salinity changes indicate broad-scale hydrological cycle and circulation changes. Global-mean sea-level change is a key indicator of the impacts of both global warming and changes in global ice volume. Furthermore, it is integral to assessing the global energy budget (Cross-Chapter Box 9.1). The oceanic overturning circulation redistributes heat, carbon, oxygen and salinity within the ocean. Declines in ocean pH result from air-sea exchange of carbon dioxide and loss of ocean oxygen results from ocean warming; both lead to changes in marine ecosystems.

Biospheric indicators

The seasonal cycle of CO_2 is an integrated measure of the biogeochemical activity across the global biosphere. Changes in marine and terrestrial ecosystems can also be observed directly at large scales. For small, free-floating organisms such as phytoplankton, the dynamics can be rapid in nature, whereas on land slower changes in plant assemblages may occur, with commensurate changes in altitude and latitude of the tree-line. Lengthening of the growing season and the associated changes in phenology, distribution and abundance of species would be expected in most of the extratropics. Biospheric indicators and their impacts

ACCEPTED VERSION SUBJECT TO FINAL EDITS

are assessed in much greater detail in WGII Chapters 2 and 3.

Defining a selection of modes of variability

Many modes of climate variability affect global, hemispheric or regional climate across a range of timescales. Conversely, their behaviour may be influenced by global climate change. Modes were selected for inclusion that: i) have effects at large spatial scales; and ii) have substantial potential to modify interannual to multidecadal climate. The selected modes are considered in multiple chapters (Cross-Chapter Box 2.2 Table 2) and are defined in Annex IV.

[START CROSS-CHAPTER BOX 2.2, TABLE 2 HERE]

Cross-Chapter Box 2.2, Table 2: Summary of the modes of variability used across Chapters 2 through 4 and their principal applications in remaining chapters. Inclusion in each of Chapters 2 through 4 is indicated by a solid fill of the relevant table cell. The list of remaining chapters is limited to those where the mode of variability is a principal consideration of that chapter and is not intended to be exhaustive.

[END CROSS-CHAPTER BOX 2.2 HERE]

2.3.1 Atmosphere and Earth's surface

2.3.1.1 Surface temperatures

2.3.1.1.1 Temperatures of the deep past (65 Ma to 8 ka)

This assessment of the paleo reference periods (Cross-Chapter Box 2.1) draws from studies based mostly or entirely on indirect observational evidence from geological archives (i.e. proxy records) rather than reconstructions that rely more heavily on modelled parameters and those based on deep-ocean temperatures (e.g. Köhler et al., 2015; Friedrich et al., 2016). In contrast to AR5, temperature estimates from climate models are not included in the assessed values for paleo reference periods in this chapter. AR5 concluded that the reconstructed GMST during the PETM was 4°C–7°C warmer than pre-PETM mean climate (*low confidence*), and that the EECO and the MPWP were 9°C–14°C and 1.9°C–3.6°C warmer than pre-industrial, respectively (*medium confidence*). The GMST during the LIG was assessed at 1°C–2°C warmer than pre-industrial (*medium confidence*), whereas SROCC narrowed the range to 0.5°C–1.0°C warmer, but did not state a confidence level. AR5 further concluded that it was *very likely* that the LGM was 3°C–8°C colder than pre-industrial, and *likely* that the maximum rate of global warming during the subsequent deglacial period was 1°C–1.5°C kyr^{-1}.

For the PETM, new reconstructions agree with those assessed by AR5. A major new compilation of proxy temperature data (Hollis et al., 2019) analysed using multiple statistical approaches (Inglis et al., 2020) indicates that GMST was 10°C–25°C (90% range) warmer than 1850–1900, or about 5°C warmer relative to the pre-PETM state. A related synthesis study also estimates that PETM warmed by 5°C (no uncertainty assigned; Zhu et al., 2019). A recent benthic isotope compilation (Westerhold et al., 2020) transformed to GMST based on the formulation by Hansen et al. (2013c) (Cross-Chapter Box 2.1, Figure 1), and adjusted to 1850-1900 by adding 0.36°C, shows an increase of GMST by about 10°C during the PETM. This reflects the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

expected higher variability at single sites that were used to splice together the composite time series, compared to the globally averaged composite time series of Zachos et al. (2008). The latter was originally used by Hansen et al. (2013c) to reconstruct GMST, and is the preferred representation of the global average bottom water conditions, despite its less well-refined chronology.

For the EECO, new GMST reconstructions fall at the high end of the range assessed by AR5. These include estimates of 7°C–18°C (90% range; Inglis et al., 2020) and 12°C–18°C (95% range; Zhu et al., 2019) warmer than 1850–1900, and 10°C–16°C warmer than 1995-2014 "recent past" conditions (2 standard error range; Caballero & Huber, 2013). Together, they indicate that GMST was 10°C–18°C warmer during the EECO compared with 1850–1900 (*medium confidence*).

AR5 did not assess the GMST for the MCO. Reconstructions based on data from multiple study sites include estimates of about 4°C (uncertainty range not specified; You et al., 2009) and 5°C–10°C (2 standard error range; Goldner et al., 2014) warmer than 1850–1900. Together, these studies indicate that GMST was 4°C–10°C warmer during the MCO (*medium confidence*).

For the MPWP, new proxy-based estimates of global sea surface temperatures (SST) are about 2.0°C–3.5°C warmer than 1850–1900, depending on which proxy types are included in the analysis (Foley and Dowsett, 2019; McClymont et al., 2020). On the basis of model-derived relationships between land versus sea surface temperatures under different climate states (Section 3.3.1.1, Figure 3.2b), the increase in GMST is estimated to have been roughly 15% greater than the increase in global SST. Therefore, GMST during the MPWP is estimated to have been 2.5°C–4.0°C warmer than 1850–1900 (*medium confidence*).

For the LIG (Cross-Chapter Box 2.1, Figure 1; Figure 2.11), a major new compilation of marine proxy data (Turney et al., 2020) from 203 sites indicates that the average SST from 129–125 ka was 1.0°C ± 0.2°C (2SD) warmer than 1850–1900 (reported relative to 1981–2010 and adjusted here by 0.8°C). These temperatures represent the time of peak warmth, which may not have been synchronous among these sites. This compares with two other SST estimates for 125 ka of 0.5°C ± 0.3°C (± 2 SD) warmer at 125 ka relative to 1870–1889 (Hoffman et al., 2017), and about 1.4°C (no uncertainty stated) warmer at 125 ka relative to 1850–1900 (Friedrich and Timmermann, 2020; reported relative to 10–5 ka and adjusted here by 0.4°C; (Kaufman et al., 2020a)). The average of these post-AR5 global SST anomalies is 1°C. Commensurately (Figure 3.2b), GMST is estimated to have been roughly 1.1°C above 1850-1900 values, although this value could be too high if peak warmth was not globally synchronous (Capron et al., 2017). A further estimate of peak GMST anomalies of 1.0°C–3.5°C (90% range; adjusted here to 1850–1900 by adding 0.2°C) based on 59 marine sediment cores (Snyder, 2016) is considerably warmer than remaining estimates and are therefore given less weight in the final assessment. The warmest millennium of the LIG GMST reconstruction in the Hansen et al. (2013c) is 1.5°C above 1850-1900. In summary, GMST during the warmest millennia of the LIG (within the interval of around 129–125 ka) is estimated to have reached 0.5°C–1.5°C higher values than the 1850–1990 reference period (*medium confidence*).

New GMST reconstructions for the LGM fall near the middle of AR5's *very likely* range, which was based on a combination of proxy reconstructions and model simulations. Two of these new reconstructions use marine proxies to reconstruct global SST that were scaled to GMST based on different assumptions. One indicates that GMST was 6.2 [4.5 to 8.1°C; 95% range] cooler than the late Holocene average (Snyder, 2016), and the other, 5.7°C ± 0.8°C (2 SD) cooler than the average of the first part of the Holocene (10–5 ka) (Friedrich and Timmermann, 2020). A third new estimate (Tierney et al., 2020) uses a much larger compilation of marine proxies along with a data-assimilation procedure, rather than scaling, to reconstruct a GMST of 6.1°C ± 0.4°C (2 SD) cooler than the late Holocene. Assuming that the 1850–1900 reference period was 0.2°C and 0.4°C cooler than the late and first part of the Holocene, respectively (Kaufman et al., 2020a), the midpoints of these three new GMST reconstructions average -5.8°C relative to 1850–1900. The coldest multi-century period of the LGM in the Hansen et al. (2013c) reconstruction is 4.3°C colder than 1850–1900. This compares to land- and SST-only estimates of about -6.1°C ± 2°C and -2.2°C ± 1°C, respectively (2 SD), which are based on AR5-generation studies that imply a warmer GMST than more recent reconstructions (Fig. 1c in Harrison et al., 2015; Fig. 7 in Harrison et al., 2016). A major new pollen-based data-assimilation reconstruction averages 6.9°C cooler over northern extratropical land (Cleator et al., 2020). LGM temperature variability on centennial scales was about four times higher globally than during

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the Holocene, and even greater at high latitudes (Rehfeld et al., 2018). In summary, GMST is estimated to have been 5°C–7°C lower during the LGM (around 23–19 ka) compared with 1850–1900 (*medium confidence*).

For the LDT (Cross-Chapter Box 2.1, Figure 1), no new large-scale studies have been published since AR5 (Shakun et al., 2012) to further assess the rate of GMST change during this period of rapid global warming (estimated at 1°C–1.5°C per kyr). The reconstruction of Shakun et al. (2012) was based primarily on SST records and therefore underrepresents the change in GMST during the LDT. Temperature over Greenland increased by about ten times that rate during the centuries of most rapid warming (Jansen et al., 2020).

2.3.1.1.2 Temperatures of the post-glacial period (past 7000 years)

AR5 did not include an assessment of large-scale temperature estimates for the MH, although it assigned *high confidence* to the long-term cooling trend over mid- to high-latitudes of the NH during the 5 kyr that preceded recent warming. For average annual NH temperatures, the period 1983–2012 was assessed as *very likely* the warmest 30-year period of the past 800 years (*high confidence*) and *likely* the warmest 30-year period of the past 1.4 kyr (*medium confidence*); the warm multi-decadal periods prior to the 20th century were unsynchronized across regions, in contrast to the warming since the mid-20th century (*high confidence*), although only sparse information was available from the SH.

This section concerns the Holocene period prior to industrialization when GMST was overall highest. Whereas SR1.5 focussed upon the 'Holocene thermal maximum' when regional temperatures were up to 1°C higher than 1850-1900, though peak warming occurred regionally at different times between around 10 and 5 ka greatly complicating interpretation. A multi-method reconstruction (Kaufman et al., 2020a) based on a quality-controlled, multi-proxy synthesis of paleo-temperature records from 470 terrestrial and 209 marine sites globally (Kaufman et al., 2020b) indicates that the median GMST of the warmest two-century-long interval was 0.7 [0.3 to 1.8] °C warmer than 1800–1900 (which averaged 0.03°C colder than 1850–1900; PAGES 2k Consortium, 2019), and was centred around 6.5 ka. This is similar to Marcott et al. (2013), which is based on a smaller dataset (73 sites) and different procedures to estimate a maximum warmth of 0.8°C ± 0.3°C (2 SD) at around 7.0 ka, adjusted here by adding 0.3°C to account for differences in reference periods. These may be underestimates because averaging inherently smoothed proxy records with uncertain chronologies reduces the variability in the temperature reconstruction (e.g., Dolman & Laepple (2018) for sedimentary archives). However, the general coincidence between peak warmth and astronomically driven boreal summer insolation might reflect a bias toward summer conditions (Bova et al., 2021; Hou et al., 2019; Liu et al., 2014), suggesting that the estimate is too high. This possibility is supported by AR5-generation proxy data focusing on 6 ka (Harrison et al., 2014), the long-standing MH modelling target (Cross-Chapter Box 2.1), that indicate surface temperatures for land and ocean were indistinguishable from 'pre-industrial' climate (Fig. 1c in Harrison et al., 2015; Fig. 7 in Harrison et al., 2016). In contrast, the GMST estimate from the multi-method global reconstruction (Kaufman et al., 2020a) for the millennium centred on 6 ka is only about 0.1°C colder than the warmest millennium.

Taking all lines of evidence into account, the GMST averaged over the warmest centuries of the current interglacial period (sometime between around 6 and 7 ka) is estimated to have been 0.2°C–1.0°C higher than 1850–1900 (*medium confidence*). It is therefore *more likely than not* that no multi-centennial interval during the post-glacial period was warmer globally than the most recent decade (which was 1.1°C warmer than 1850–1900; Section 2.3.1.1.3); the LIG (129–116 ka) is the next most recent candidate for a period of higher global temperature. Zonally averaged mean annual temperature reconstructions (Routson et al., 2019) indicate that MH warmth was most pronounced north of 30°N latitude, and that GMST subsequently decreased in general, albeit with multi-century variability, with greater cooling in the NH than in the SH (Kaufman et al., 2020a).

The temperature history of the last millennium and the methods used to reconstruct it have been studied extensively, both prior to and following AR5, as summarized recently by Smerdon and Pollack (2016) and Christiansen and Ljungqvist (2017). New regional (e.g., Shi et al., 2015; Stenni et al., 2017; Werner et al., 2018), global ocean (McGregor et al., 2015), quasi-hemispheric (Neukom et al., 2014; Schneider et al., 2015;

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Anchukaitis et al., 2017), and global (Tardif et al., 2019) temperature reconstructions, and new regional proxy data syntheses (Lüning et al., 2019a,b) have been published, extending back 1-2 kyr. In addition, a major new global compilation of multiproxy, annually resolved paleo-temperature records for the CE (PAGES 2k Consortium, 2017) has been analysed using a variety of statistical methods for reconstructing temperature (PAGES 2k Consortium, 2019). The median of the multi-method GMST reconstruction from this synthesis (Figure 2.11a) generally agrees with the AR5 assessment, while affording more robust estimates of the following major features of GMST during the CE: (1) an overall millennial-scale cooling trend of –0.18 [–0.28 to 0.00] °C kyr^{-1} prior to 1850; (2) a multi-centennial period of relatively low temperature beginning around the 15th century, with GMST averaging –0.03 [–0.30 to 0.06] °C between 1450 and 1850 relative to 1850–1900; (3) the warmest multi-decadal period occurring most recently; and (4) the rate of warming during the second half of the 20th century (from instrumental data) exceeding the 99th percentile of all 51-year trends over the past 2 kyr. Moreover, the new proxy data compilation shows that the warming of the 20th century was more spatially uniform than any other century-scale temperature change of the CE (*medium confidence*) (Neukom et al., 2019). A new independent temperature reconstruction extending back to 1580 is based on an expanded database of subsurface borehole temperature profiles, along with refined methods for inverse modelling (Cuesta-Valero et al., 2021). The borehole data, converted to GMST based on the modelled relation between changes in land versus sea surface temperature outlined previously, indicate that average GMST for 1600–1650 was 0.12°C colder than 1850–1900, which is similar to the PAGES 2k reconstruction (0.09°C colder), although both estimates are associated with relatively large uncertainties (0.8°C (95% range) and 0.5°C (90% range), respectively).

To conclude, following approximately 6 ka, GMST generally decreased, culminating in the coldest multi-century interval of the post-glacial period (since 8 ka), which occurred between around 1450 and 1850 (*high confidence*). This multi-millennial cooling trend was reversed in the mid-19th century. Since around 1950, GMST has increased at an observed rate unprecedented for any 50-year period in at least the last 2000 years (*medium confidence*).

[START FIGURE 2.11 HERE]

Figure 2.11: Earth's surface temperature history with key findings annotated within each panel. (a) GMST over the Holocene divided into three time scales. (i) 12 kyr–1 kyr in 100-year time steps, (ii) 1000–1900 CE, 10-year smooth, and (iii) 1900–2020 CE (from panel c). Median of the multi-method reconstruction (bold lines), with 5th and 95th percentiles of the ensemble members (thin lines). Vertical bars are the assessed *medium confidence* ranges of GMST for the Last Interglacial and mid-Holocene (Section 2.3.1.1). The last decade value and *very likely* range arises from 2.3.1.1.3. (b) Spatially resolved trends (°C per decade) for HadCRUTv5 over (upper map) 1900–1980, and (lower map) 1981–2020. Significance is assessed following AR(1) adjustment after Santer et al., (2008a), 'x' marks denote non-significant trends. (c) Temperature from instrumental data for 1850–2020, including (upper panel) multi-product mean annual timeseries assessed in Section 2.3.1.1.3 for temperature over the ocean (blue line) and temperature over the land (red line) and indicating the warming to the most recent 10 years; and annually (middle panel) and decadally (bottom panel) resolved averages for the GMST datasets assessed in Section 2.3.1.1.3. The grey shading in each panel shows the uncertainty associated with the HadCRUT5 estimate (Morice et al., 2021). All temperatures relative to the 1850–1900 reference period. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

This Cross-Chapter Box presents the AR6 WGI assessment of observed global warming and describes improvements and updates since AR5 and subsequent Special Reports. The revised estimates result from: the availability of new and revised observational datasets; the occurrence of recent record warm years; and the evaluation of the two primary metrics used to estimate global warming in past IPCC reports: "Global mean surface temperature" (GMST) and "Global surface air temperature" (GSAT). Implications for threshold crossing times, remaining carbon budgets and impacts assessments across AR6 WGs are discussed.

Dataset innovations

Since AR5, all major datasets used for assessing observed temperature change based upon GMST have been updated and improved (Section 2.3.1.1.3). A number of new products have also become available, including new datasets (e.g. Berkeley Earth, Rohde & Hausfather, 2020) and new interpolations based on existing datasets (e.g. Cowtan and Way (2014) and Kadow et al. (2020a)). These various estimates are not fully independent.

Improvements in global temperature datasets since AR5 have addressed two major systematic issues. First, new SST datasets (Huang et al., 2017; Kennedy et al., 2019) address deficiencies previously identified in AR5 relating to the shift from predominantly ship-based to buoy-based measurements; these improvements result in larger warming trends, particularly in recent decades. Second, all datasets now employ interpolation to improve spatial coverage. This is particularly important in the Arctic, which has warmed faster than the rest of the globe in recent decades (Atlas 5.9.2.2); under-sampling of the Arctic leads to a cool bias in recent decades (Simmons et al., 2017; Benestad et al., 2019). Some datasets are now spatially complete (Cowtan and Way, 2014; Kadow et al., 2020a) while others have expanded spatial coverage (Lenssen et al., 2019; Morice et al., 2021; Rohde & Hausfather, 2020; Vose et al., 2021). Several interpolation methods have been benchmarked against test cases (e.g. Lenssen et al., 2019), and comparisons with reanalyses further confirm the value of such interpolation (Simmons et al., 2017). It is *extremely likely* that interpolation produces an improved estimate of the changes in GMST compared to ignoring data-void regions.

Overall, dataset innovations and the availability of new datasets have led to an assessment of increased GMST change relative to the directly equivalent estimates reported in AR5 (Cross-Chapter Box 2.3, Table 1 and Figure 1).

Effects of warming since AR5 and choice of metrics of global mean temperature change

Each of the six years from 2015 to 2020 has *likely* been warmer than any prior year in the instrumental record. GMST for the decade 2011–2020 has been 0.19 [0.16 to 0.22] °C warmer than 2003–2012, the most recent decade used in AR5 (Cross-Chapter Box 2.3, Figure 1). A linear trend has become a poorer representation of observed change over time since most of the sustained warming has occurred after the 1970s (Cross-Chapter Box 2.3 Figure 1) and all values since 2012 are at least 0.2°C above a linear trendline for 1850–2020. For this reason, the primary method used to assess observed warming in this report is the change in temperature from 1850–1900 to the most recent decade (2011–2020) or the recent past (1995–2014), replacing the trend-based methods used in AR5 and earlier assessments. The effect of this change from trend-based to change-based metrics is currently relatively minor at -0.03°C (<5%) for the most recent decade, but this may not remain the case in future (*high confidence*).

Observed changes in global mean temperature since the pre-industrial era

AR5 used 1850–1900 as an approximate pre-industrial baseline for global temperature change, whilst using an earlier pre-industrial baseline of 1750 for radiative forcings. Cross-Chapter Box 1.2 assesses that there

ACCEPTED VERSION SUBJECT TO FINAL EDITS

was an observed GMST change from the period around 1750 to 1850–1900 of around 0.1°C (*likely* range -0.1 to +0.3°C, *medium confidence*). This additional global temperature change before 1850–1900 is not included when making AR6 assessments on global warming to date, global temperature threshold crossing times, or remaining carbon budgets to ensure consistency with previous ARs.

Addressing the non-equivalence of GMST and GSAT

GMST is a combination of land surface air temperatures (LSAT) and SSTs, whereas GSAT is a combination of LSAT and marine air temperatures (MATs). Although GMST and GSAT are closely related, the two measures are physically distinct. The implications have become more apparent since AR5 (Cowtan et al., 2015; IPCC, 2018 (SR1.5); Merchant et al., 2013; Richardson et al., 2018; Simmons et al., 2017), and it has been shown (Rubino et al., 2020) that MAT and SST can show distinct multidecadal-scale trends and patterns of interannual variability. Although the SR1.5 used GMST for observational-based and GSAT for model-based headline warming statements, they noted the importance of the difference for their assessment (SR1.5 Section 1.2.1.1). SR1.5 used information from CMIP5 models to estimate a GSAT equivalent from observation-based GMST for certain applications such as remaining carbon budgets. The following subsections assess available lines of evidence related to the equivalence between GMST and GSAT.

Physical understanding

A well-understood physical constraint on the vertical gradient between the air and sea surface temperature is that it is approximately proportional to the turbulent sensible heat flux in the atmospheric surface layer (Chor et al., 2020). Similarly, the latent heat flux scales with the vertical humidity gradient and, in the global mean and in most oceanic regions, the latent heat flux is substantially larger than the sensible heat flux (Sections 7.2.1, 9.2.1.3). If GSAT were to warm faster than GMST, the sensible surface heat flux would respond so as to reduce this difference. However, it is the sum of the sensible, latent, and radiative heat fluxes that controls GMST, so the sensible heat flux effect cannot be considered in isolation. Attempts to further constrain the combination of fluxes (e.g., Lorenz et al., 2010; Siler et al., 2019) rely on parameterisations or output from Earth system models (ESMs) or reanalyses and so are not considered independent. Apart from the above global considerations, regional and seasonal effects such as changes to the frequency and intensity of storms, sea state, cloudiness, sea ice cover, vegetation and land use may all affect the GSAT to GMST difference, either directly or by altering the relationships between gradients and energy fluxes. These changing energy flux relationships are monitored through observing the stratification of the upper ocean (Section 9.2.1.3) and the response of upper ocean processes (Cross-Chapter Box 5.3) in ESMs and reanalyses, but such monitoring tasks rival the observational challenge of directly observing SSTs and 2 m air temperature under a wide range of conditions. In summary, because of the lack of physical constraints and the complexity of processes driving changes in the GSAT to GMST temperature differences, there is no simple explanation based on physical grounds alone for how this difference responds to climate change.

Direct observational evidence

There is currently no regularly updated, entirely observation-based dataset for GSAT. The best available observations of near-surface air temperature over ocean are datasets of night-time marine air temperature (NMAT) (e.g. Cornes et al., 2020; Junod & Christy, 2020), though spatial coverage is less extensive than for SST. Night-time measurements are used to avoid potential biases from daytime heating of ship superstructures. Kennedy et al. (2019) show little difference between HadNMAT2 and HadSST4 between 1920 and 1990, but a warming of SST relative to NMAT manifesting as a step change of 0.05°C–0.10°C in the early 1990s, which may reflect an actual change, the impact of increasingly divergent spatial coverage between SST and MAT measurements, or unresolved structural uncertainties in one or both datasets. This leads to NMAT warming around 10% more slowly than SST over the last century. In contrast, Junod and Christy (2020a) find NMAT trends which are 8–17% larger than those for SST in the ERSSTv4 and HadISST datasets for the period 1900 to 2010, but 11–15% smaller than the SST trends for the same datasets from 1979 to 2010. However, ERSSTv4 uses NMAT data as a basis for homogeneity adjustment so is not fully independent. Kent and Kennedy (2021) note sensitivity to methodological choices in comparisons but find that NMAT is warming more slowly than SST products over most periods considered. Rubino et al.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(2020) exploit tropical Pacific moored buoy arrays, available since the early 1980s, and find differences in NMAT and SST anomalies, which are sensitive to the choice of period and show spatio-temporal ENSO-related (Annex IV) signals in the differences.

Overall, with *medium evidence* and *low agreement*, available observational products suggest that NMAT is warming less than SST by up to 15%. Given that these ocean observations cover roughly two thirds of the globe, this implies that GMST is warming up to at most 10% faster than GSAT. Substantial uncertainty remains and the effect is highly sensitive to the choice of both time period and choice of NMAT and SST observational products to compare. Observed NMAT warming faster than observed SST cannot be precluded.

CMIP model-based evidence

CMIP historical simulations and projections agree that GSAT increases faster than GMST, the reverse of what is indicated by many marine observations. Several studies approximate the approach used to derive GMST from observations by blending SST over open ocean and SAT over land and sea ice from model output (Cowtan et al., 2015; Richardson et al., 2018; Beusch et al., 2020; Gillett et al., 2021). Cowtan et al. (2015) found that trends in GSAT are of the order of 9% larger than for GMST in CMIP5, based on data from 1850–2100 (historical + RCP8.5), if anomalies are blended and sea ice is allowed to vary over time. Broadly consistent numbers are found for both CMIP5 and CMIP6, across a range of SSP and RCP scenarios and time periods (Richardson et al., 2018; Beusch et al., 2020; Gillett et al., 2021). Blending monthly anomalies and allowing sea ice to vary, the change in GSAT for 2010–2019 relative to 1850–1900 is 2–8% larger than spatially-complete GMST in CMIP6 historical and SSP2-4.5 simulations (Gillett et al., 2021), and 6–12% larger in CMIP5 historical and RCP2.6 and 8.5 simulations for 2007–2016 relative to 1861–1880 (Richardson et al., 2018). However, a true like-for-like comparison to observational products is challenging because methodological choices have a large impact on the relationship between modelled GMST and GSAT and none of these studies fully reproduces the methods used to derive estimates of GMST in recent observational datasets, which use various ways to infill areas lacking in situ observations (Jones, 2020).

Marine boundary layer behaviour and parameterisations in all CMIP models are based upon Monin-Obukhov similarity theory (e.g. Businger et al., 1971), which informs assumptions around gradients in the near-surface boundary layer dependent upon temperature, wind speed and humidity. This leaves open the possibility of a common model bias, while Druzhinin et al. (2019) also point to departures of temperature profiles from theoretical predictions under certain conditions. There remain inadequacies in understanding and modelling of key processes (Edwards et al., 2020), and biases in the representation of the absolute SST-MAT difference have been identified in climate models and reanalyses (Găinuşă-Bogdan et al., 2015; Zhou et al., 2020).

Reanalysis-based evidence

Simmons et al. (2017) found that in JRA-55 and ERA-Interim (following an adjustment to account for an apparent discontinuity), GSAT increased 2–4% faster than GMST over the period 1979–2016.
In atmospheric reanalyses, SST is given as a lower boundary condition from an observed globally interpolated product (such as HadISST; Rayner et al., 2003) whereas the air temperature is reliant upon model parameterisations and assimilated observations that do not include MAT observations (Simmons et al., 2017), thereby limiting their capability to constrain differences in GMST and GSAT trends. Furthermore, it is unclear what the lack of dynamic coupling at the ocean-atmosphere interface might imply for the representativeness of reanalysis-based estimates.

Representation of surface temperatures in sea ice regions

There is a significant issue in areas where sea-ice melts or grows, where the quantity used in observational-based GMST estimates switches between air temperature and sea surface temperature. This primarily affects analyses combining SAT anomalies over land and ice with SST anomalies over ocean. In areas where sea ice has recently melted, the climatological value changes from an air-temperature based estimate to an SST estimate based upon the freezing point of seawater (–1.8°C). This switch in climatology to, in general, a warmer climatology, leads to a bias towards reduced warming in anomalies compared with analyses based

ACCEPTED VERSION SUBJECT TO FINAL EDITS

on absolute temperatures. Richardson et al. (2018) found this underestimation to amount to approximately 3% of observed warming in historical model simulations. Given the projected future sea-ice losses, the effect will grow in future (*low confidence*), with potential effects of the order of 0.1°C in the second half of the 21st century under high warming scenarios, although with some uncertainty arising from the large spread of sea-ice loss in model projections (Tokarska et al., 2019).

Summary of lines of evidence

GMST and GSAT are physically distinct. There is *high confidence* that long-term changes in GMST and GSAT differ by at most 10% in either direction. However, conflicting lines of evidence from models and direct observations combined with limitations in theoretical understanding lead to *low confidence* in the sign of any difference in long-term trends. The *very likely* range of estimated historical GMST warming is combined with the assessed ± 10% uncertainty in the relationship between GMST and GSAT changes to infer a GSAT equivalent, accounting for any possible real-world physical difference. Improvements in understanding may yield a robust basis to apply a scaling-factor to account for the difference in future assessments.

[START CROSS-CHAPTER BOX 2.3, TABLE 1 HERE]

Cross Chapter Box 2.3, Table 1: Summary of key observationally-based global warming estimates (in °C) to various periods in the present report and selected prior reports and their principal applications. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

Period	**AR6 GMST (°C)**	**AR6 GSAT* (°C)**	**AR5 and / or *SR1.5* (only where reported) (°C)**	**Principal use of this period in reports**
1850–1900 to 2011–2020	1.09 (0.95–1.20)	1.09 (0.91–1.23)		Warming to present in AR6 WGI
1850–1900 to 2010–2019	1.06 (0.92–1.17)	1.06 (0.88–1.21)		Attributable warming in AR6 WGI
1850–1900 to 2006–2019	1.03 (0.89–1.14)	1.03 (0.86–1.18)		Energy budget constraints in AR6 on ECS and TCR
1850–1900 to 2006–2015	0.94 (0.79–1.04)	0.94 (0.76–1.08)	*0.87 (0.75–0.99) - GMST* *0.97 (0.85–1.09) – GSAT*[#]	Warming to date in SR1.5. GSAT value used for remaining carbon budgets (RCBs) in SR1.5.
1850–1900 to 2003–2012	0.90 (0.74–1.00)	0.90 (0.72–1.03)	0.78 (0.72–0.85)	Warming to date in AR5 WGI.
1850–1900 to 1995–2014	0.85 (0.69–0.95)	0.85 (0.67–0.98)		Warming to recent past in AR6 WGI.

1850–1900 to 1986–2005	0.69 (0.54–0.79)	0.69 (0.52–0.82)	0.61 (0.55–0.67)^	Warming to recent past in AR5 WGI.
1850–1900 to 1961–1990	0.36 (0.23–0.44)	0.36 (0.22–0.45)		Warming to reference period recommended by WMO for national-level data sets used for climate change assessment (included in the WGI Atlas)
1880–2012 OLS trend	0.92 (0.68–1.17)		0.85 (0.65–1.06)	Warming to date in AR5 WGI

* As the uncertainty in the relationship between GMST and GSAT changes is independent of the uncertainty in the assessed change in GMST, these uncertainties are combined in quadrature.
SR1.5 derived a GSAT estimate by taking the CMIP5 ensemble mean GSAT change of 0.99°C, sub-sampling to HadCRUTv4.6, noting the offset in trends (0.84°C HadCRUT4 observed GMST vs. 0.86°C modelled GMST) and adjusting by this to arrive at an estimate of 0.97 °C change in GSAT. The *likely* uncertainty range of ±0.12°C was not further adjusted.
^ Note that the AR5 approach for the change from 1850–1900 to both 1986–2005 and 2003–2012 was based upon one dataset (HadCRUT4) and its parametric uncertainty estimates are known to underestimate the true uncertainty.

[END CROSS-CHAPTER BOX 2.3, TABLE 1 HERE]

Mapping between AR5 and AR6 assessments

The AR5 assessed estimate for historical warming between 1850–1900 and 1986–2005 is 0.61 [0.55 to 0.67] °C. The equivalent in AR6 is 0.69 [0.54 to 0.79] °C, and the 0.08 [-0.01 to 0.12] °C difference is an estimate of the contribution of changes in observational understanding alone (Cross-Chapter Box 2.3, Table 1). The exact value of this contribution depends upon the metric being compared (GMST/GSAT, trend or change, exact period). The AR6-assessed GMST warming between 1850–1900 and 2011–2020 is 1.09 [0.95 to 1.20] °C. An AR5-equivalent assessment using this estimated difference in observational understanding is thus 1.01 [0.94 to 1.08] °C. These updates and improvements in observational datasets affect other quantities that derive from the assessment of GSAT warming, including estimates of remaining carbon budgets and estimates of crossing times of 1.5°C and 2°C of global warming (See Cross Chapter Box 2.3 Table 1**).**

Updates to estimated Global Warming Level (GWL) crossing times

The updated estimate of historical warming is one contribution to the revised time of projected crossing of the threshold of 1.5°C global warming in comparison with SR1.5, but is not the only reason for this update. The AR6 assessment of future change in GSAT (Section 4.3.4, Table 4.5) results in the following threshold-crossing times, based on 20-year moving averages. The threshold-crossing time is defined as the midpoint of the first 20-year period during which the average GSAT exceeds the threshold. During the near term (2021–2040), a 1.5°C GSAT increase relative to the average over the period 1850–1900 is *very likely* to occur in scenario SSP5-8.5, *likely* to occur in scenarios SSP2-4.5 and SSP3-7.0, and *more likely than not* to occur in scenarios SSP1-1.9 and SSP1-2.6. In all scenarios assessed here except SSP5-8.5, the central estimate of crossing the 1.5°C global warming level lies in the early 2030s. This is about ten years earlier than the midpoint of the *likely* range (2030–2052) assessed in the SR1.5, which assumed continuation of the then-reported warming rate; this estimated rate has been confirmed in AR6 (Section 3.3.1). Roughly half of the ten-year difference arises from the higher diagnosed historical warming in AR6. The other half arises because, for central estimates of climate sensitivity, most scenarios show stronger warming over the near term than was assessed as 'current' in SR1.5 (*medium confidence*).

Implications for assessment of emission scenarios and remaining carbon budgets

To estimate the global warming implications of emissions scenarios, AR5 and SR1.5 combined estimates of observed GMST changes from 1850–1900 to 1986–2005 (Cross-Chapter Box 2.3, Table 1) with GSAT projections of subsequent warming. AR6 undertakes three changes to this approach. First, the AR6

ACCEPTED VERSION SUBJECT TO FINAL EDITS

assessment of improved observational records is used. Second, the recent past baseline period is updated from 1986–2005 to 1995–2014, and, third, historical estimates are expressed in GSAT instead of GMST for consistency of historical estimates with future projections. The updated estimates of warming to date in AR6 lead to higher estimates of future warming, all else being equal. The temperature classification of emissions scenarios in the WGIII report adopts the definition of temperature classes as introduced in SR1.5, and assigns emission scenarios to these classes based on their AR6 assessed GSAT outcomes (Cross-Chapter Box 7.1, WGIII Annex C.II.2.4).

Both in AR5 and SR1.5, remaining carbon budgets were expressed as a function of GSAT warming, while also highlighting the implications of using historical warming estimates expressed in GMST. AR5 reported total carbon budgets for GSAT warming relative to 1861–1880. AR5 SYR also includes remaining carbon budget estimates based on AR5 WGIII scenario projections that use the method for AR5 scenario projections described above. SR1.5 integrated several methodological advancements to estimate remaining carbon budgets and reported budgets for additional GSAT warming since the 2006–2015 period, estimating, following the application of an adjustment (Richardson et al., 2016, Table 1.1. SR1.5) to GMST, that 0.97°C (± 0.12°C) of GSAT warming occurred historically between 1850–1900 and 2006–2015. The AR6 assessment, above, leads to an estimate of 0.94°C of warming between 1850–1900 and 2006–2015. All other factors considered equal, the AR6 estimate thus implies that 0.03°C more warming is considered for remaining carbon budgets compared to SR1.5. Combining this 0.03°C value with the SR1.5 transient climate response to cumulative emissions of CO_2 (TCRE) translates into remaining carbon budgets about 70 $GtCO_2$ [40 to 140 $GtCO_2$] larger compared to SR1.5 on a like-for-like basis. Meanwhile, on the same like-for-like basis, updates to historical observational products would reduce remaining carbon budgets reported in AR5 SYR based on WGIII scenario projections by about 180 $GtCO_2$ [120 to 370 $GtCO_2$]. Box 5.2 provides a further overview of updates to estimates of the remaining carbon budget since AR5.

Implications for assessment of impacts and adaptation

The assessment of global warming to date now being larger than previously assessed has no consequence on the assessment of past climate impacts, nor does it generally imply that projected climate impacts are now expected to occur earlier. The implications are mainly that the level of warming associated with a particular impact has been revised. This has very limited practical implications for the assessment of the benefits of limiting global warming to specific levels, as well as for the urgency of adaptation action. For example, impacts that occurred in the period 1986–2005 were previously associated with a GMST increase of 0.61°C relative to 1850–1900, relative to AR5 estimates. These impacts are now instead associated with a GMST increase of 0.69°C, relative to the assessment in this Report. The impacts themselves have not changed. Similarly, the impacts previously associated with a GMST or GSAT increase of 1.5°C will now generally be associated with a slightly different global warming level. This is because projections of future warming and its impacts relative to 1850–1900 are normally made by adding projected warming from a recent past baseline to an estimate of the observed warming from 1850–1900, as in AR5 and SR1.5.

Most of the previously projected impacts and risks associated with global warming of 1.5°C have therefore not changed and are still associated with the same level of future warming (0.89°C) relative to 1986–2005. With this warming now estimated as 0.08°C larger than in AR5, the future impacts previously associated with 1.5°C warming are now associated with 1.58°C warming. Similarly, the impacts now associated with 1.5°C warming would have previously been associated with 1.42°C warming. There are exceptions where impacts studies have used a baseline earlier than 1986–2005 (e.g. King et al., 2017), for which the new estimate of the historical warming would mean an earlier occurrence of the projected impacts. However, even in these cases, the ostensible difference in impacts associated with a 0.08°C difference in global mean temperature will be small in comparison with the uncertainties. There are also substantial uncertainties in regional climate changes and the magnitude of climate impact-drivers projected to occur with global warming of 1.5°C (Betts et al., 2018; Seneviratne et al., 2018). Furthermore, the time of reaching global warming of 1.5°C is subject to uncertainties of approximately ± 10 years associated with uncertainties in climate sensitivity, and ± 3 to 4 years associated with the different SSP forcing scenarios (Section 4.3.4, Table 4.5 see prior discussion). There is therefore *high confidence* that assessment of the magnitude and timing of impacts-related climate quantities at 1.5°C is not substantially affected by the revised estimate of

ACCEPTED VERSION SUBJECT TO FINAL EDITS

historical global warming.

The assessment of the implications of limiting global warming to 1.5°C compared to 2°C will also remain broadly unchanged by the updated estimate of historical warming, as this depends on the relative impacts rather than the absolute impacts at any specific definition of global temperature anomaly *(high confidence)*.

[END CROSS-CHAPTER BOX 2.3 HERE]

2.3.1.1.3 Temperatures during the instrumental period – surface

AR5 concluded that it was certain that GMST had increased since the late 19th century. Total warming in GMST was assessed as 0.85 [0.65 to 1.06] °C over 1880–2012, whilst the change from 1850–1900 to 2003–2012 was assessed at 0.78 [0.72 to 0.85] °C, and from 1850–1900 to 1986–2005 at 0.61 [0.55 to 0.67] °C. SR1.5 reported warming of GMST from 1850–1900 to 2006–2015 of 0.87°C, with an 1880–2012 trend of 0.86°C and an 1880–2015 trend of 0.92°C. SRCCL concluded that since the pre-industrial period, surface air temperature over land areas has risen nearly twice as much as the global mean surface temperature (*high confidence*).

Since AR5, there have been substantial improvements in the availability of instrumental archive data both over the ocean and on land. A new version of the International Comprehensive Ocean-Atmosphere Dataset (ICOADS Release 3.0, Freeman et al., 2017) comprises over 450 million in situ marine reports and incorporates newly digitised data, increasing coverage in data sparse regions and times (e.g. polar oceans and World War I). The International Surface Temperature Initiative released a much improved collection of fundamental land surface air temperature records (Rennie et al., 2014) comprising more than 35,000 station records. These advances, both of which have substantially improved spatial coverage, have reduced uncertainties in assessments of both land and marine data.

Marine domain

For SST analyses, three products – HadSST4 (1850–present, Kennedy et al., 2019), ERSSTv5 (1850–present, Huang et al., 2017) and COBE SST2 (1880–present, (Hirahara et al., 2014) – now have bias adjustments applied throughout the record. The new SST datasets account for two major issues previously identified in AR5: that globally averaged buoy SSTs are about 0.12°C cooler than ship-based SSTs (Huang et al., 2015; Kennedy et al., 2011), and that SSTs from ship engine room intakes may have biases for individual ships depending upon the sensor set-up (Kent & Kaplan, 2006) but have an overall warm bias when globally aggregated (Kennedy et al., 2019). The first issue primarily affects data since 1990, when buoys began to increasingly contribute to the observation network (Woodruff et al., 2011), and the second issue has its largest effect from the 1940s to the 1970s. From the standpoint of uncertainty, ERSSTv4 (Liu W. et al., 2015a; Huang et al., 2016) and subsequent versions (Huang et al., 2017), and HadSST4 have

ACCEPTED VERSION SUBJECT TO FINAL EDITS

estimates presented as ensembles that sample parametric uncertainty. Comparisons between these independently-derived analyses and the assessed uncertainties (Kennedy, 2014; Kent et al., 2017) show unambiguously that global mean SST increased since the start of the 20th century, a conclusion that is insensitive to the method used to treat gaps in data coverage (Kennedy, 2014).

A number of recent studies also corroborate important components of the SST record (Cowtan et al., 2018; Hausfather et al., 2017; Kennedy et al., 2019; Kent et al., 2017). In particular, ATSR SST satellite retrievals (Merchant et al., 2012; Berry et al., 2018), the near-surface records from hydrographical profiles (Gouretski et al., 2012; Huang et al., 2018), and coastal observations (Cowtan et al., 2018) have all been shown to be broadly consistent with the homogenized SST analyses. Hausfather et al. (2017) also confirmed the new estimate of the rate of warming seen in ERSSTv4 since the late 1990s through comparison with independent SST data sources such as Argo floats and satellite retrievals. Nevertheless, dataset differences remain in the mid-20th century when there were major, poorly-documented, changes in instrumentation and observational practices (Kent et al., 2017), particularly during World War II, when ship observations were limited and disproportionately originated from US naval sources (Thompson et al., 2008). Kennedy et al. (2019) also identify differences between the new HadSST4 dataset and other SST datasets in the 1980s and 1990s, indicating that some level of structural uncertainty remains during this period, whilst Chan et al. (2019) and Davis et al. (2019) document residual uncertainties in the early and later 20th century records respectively.

Historically, SST has been used as a basis for global temperature assessment on the premise that the less variable SST data provides a better estimate of marine temperature changes than marine air temperature (MAT) (Kent & Kennedy, 2021). However, MAT products are used to adjust SST biases in the NOAA SST product because they are assessed to be more homogeneous (Huang et al., 2017). Observational datasets exist for night-marine air temperature (NMAT) (e.g. (Cornes et al., 2020; Junod & Christy, 2019; Rayner et al., 2020) and there are methods to adjust daytime MATs (Berry et al., 2004), but there is to date no regularly updated dataset which combines MAT with temperatures over land. MAT datasets are more sparse in recent decades than SST datasets as marine datasets have become increasingly dependent on drifting buoys (Centurioni et al., 2019) which generally measure SST but not MAT, and there are almost no recent winter MAT data south of 40°S (Swart et al., 2019). However, the situation reverses in the 19th Century with a greater prevalence of MAT than SST measurements available in the ICOADS data repository (Freeman et al., 2017, 2019; Kent & Kennedy, 2021).

Land domain

The GHCNMv4 dataset (Menne et al., 2018) includes many more land stations than GHCNMv3, arising from the databank efforts of Rennie et al. (2014), and calculates a 100-member parametric uncertainty ensemble drawing upon the benchmarking analysis of Williams et al. (2012), as well as accounting for sampling effects. A new version of the CRUTEM dataset (CRUTEMv5, Osborn et al., 2021) has increased data completeness and additional quality control measures. A new global land dataset, the China Land Surface Air Temperature (CLSAT) dataset (Xu et al., 2018) has higher network density in some regions (particularly Asia) than previously existing datasets. Global trends derived from CLSAT are generally consistent with those derived from other land datasets through 2014 (Xu et al., 2018).

AR5 identified diurnal temperature range (DTR) as a substantial knowledge gap. The most recent analysis of Thorne et al. (2016a,b) compared a broad range of gridded estimates of change in DTR, including a new estimate derived from the ISTI databank release using the pairwise homogenization algorithm used to create GHCNMv4, and estimates derived from the Vose et al. (2005), HadEX2 (Donat et al., 2013a), HadGHCND (Donat et al., 2013a), GHCNDEX (Donat et al., 2013b), Berkeley Earth (Rohde et al., 2013), and CRU TS (Harris et al., 2014). The analysis highlighted substantial ambiguity in pre-1950 estimates arising from sparse data availability. After 1950 estimates agreed that DTR had decreased globally with most of that decrease occurring over the period 1960–1980. A subsequent DTR analysis using CLSAT further confirmed this behaviour (Sun et al., 2018).

No recent literature has emerged to alter the AR5 finding that it is *unlikely* that any uncorrected effects from urbanization (Box 10.3), or from changes in land use or land cover (Section 2.2.7), have raised global Land Surface Air Temperature (LSAT) trends by more than 10%, although larger signals have been identified in

ACCEPTED VERSION SUBJECT TO FINAL EDITS

some specific regions, especially rapidly urbanizing areas such as eastern China (Li Y. et al., 2013; Liao et al., 2017; Shi et al., 2019). There is also no clear indication that site-specific data homogeneity issues have had any significant impact on global trends since the early 20th century; there is more uncertainty in the 19th century, mainly arising from a lack of standardization of instrument shelters, which has been largely accounted for in data from central Europe (Jones et al., 2012), but less so elsewhere.

Combined data products

At the time of AR5 a limitation of conventional datasets was the lack of coverage, especially in high latitudes, which although recognised as an issue (Simmons et al., 2010a) had not been addressed in most products. Interpolation involves the statistical imputation of values across regions with limited data and can add both systematic and random uncertainties (Lenssen et al., 2019). Cowtan and Way (2014) applied a kriging-based method to extend existing datasets to polar regions, while Kadow et al. (2020a) used an artificial intelligence-based method, and Vaccaro et al. (2021) used gaussian random Markov fields, for the same purpose, although only Kadow et al. (2020) uses the most recent generation of datasets as its base. The Berkeley Earth merged product (Rohde & Hausfather, 2020), HadCRUT5 (Morice et al., 2021) and NOAA GlobalTemp - Interim (Vose et al., 2021) all include interpolation over reasonable distances across data sparse regions which results in quasi-global estimates from the late 1950s when continuous Antarctic observations commenced. Interpolated datasets with substantial coverage of high latitudes show generally stronger warming of GMST than those with limited data in polar regions (Vose et al., 2021), and their strong warming at high northern latitudes is consistent with independent estimates from reanalyses (Simmons et al., 2017; Lenssen et al., 2019) and satellites (Cowtan and Way, 2014). Given the spatial scales of surface temperature variations and the verification of the methods, it is *extremely likely* that interpolation results in a less-biased estimate of the actual global temperature change than ignoring regions with limited or no data.

In total there are five conventional datasets which meet spatial coverage requirements and draw from the most recent generation of SST analyses, four of which have sufficient data in the 1850–1900 period to allow an assessment of changes from that baseline (Table 2.3). A fifth dataset is added to the assessment for changes over land areas. Datasets share SST and LSAT data products and in several cases differ solely in the post-processing interpolation applied meaning that there are far fewer methodological degrees of freedom than implied by a straight count of the number of available estimates.

[END TABLE 2.3 HERE]

Estimates of GMST have also benefitted from improved estimation of parametric uncertainties. New versions of three long-standing products from NASA GISTEMP v4 (Lenssen et al., 2019), NOAA GlobalTempv5 (Huang et al., 2019) and HadCRUT5 (Morice et al., 2021) are all now available as ensemble estimates. These ensembles each account for a variety of systematic and random uncertainty effects in slightly different ways, giving broadly similar results, which are incorporated into the present assessment, with the total uncertainty generally declining up until the mid-20th century as data coverage improves.

Another significant development has been the incorporation of reanalysis products (Section 1.5.2) into operational monitoring of GSAT. It was reported in AR5 that various reanalyses were broadly consistent with conventional surface datasets in the representation of trends since the mid-20th century. Since that time, Simmons et al. (2017) found that the ERA-Interim (Dee et al., 2011) and JRA-55 (Kobayashi et al., 2015) reanalyses continued to be consistent, over the last 20 years, with those surface datasets which fully represented the polar regions. GSAT trends from ERA5 reanalysis (Hersbach et al., 2020) are also broadly consistent with GMST trends from conventional surface datasets. However, the MERRA-2 reanalysis (Gelaro et al., 2017) GSAT spuriously cooled sharply relative to ERA-Interim and JRA-55 in about 2007 (Funk et al., 2019). Since the early 2000s, analyses of surface temperature, from which near-surface temperature may be derived, have also been available from various satellites (Famiglietti et al., 2018; Prakash et al., 2018; Susskind et al., 2019), which have the potential to improve assessments of temperature changes over data-sparse regions.

Most land areas in the extratropical NH have warmed faster than the GMST average over both the 1900–2020 and 1980–2020 periods (Figure 2.11b), although at more regional scales, particularly in data sparse regions, considerable uncertainty is introduced by sometimes large differences in trends between different LSAT datasets (Rao et al., 2018). Temperatures averaged over land areas globally have warmed by 1.59 [1.34 to 1.83] °C from 1850–1900 to 2011–2020, substantially higher than the SST warming of 0.88 [0.68 to 1.01] °C. The four conventional surface temperature products which meet all criteria to be included in the final assessment (Table 2.4) agree that each of the last four decades has consecutively been the warmest globally since the beginning of their respective records (Figure 2.11c, Table 2.4). Each of the six years 2015 to 2020 has *very likely* been at least 0.9°C warmer than the 1850–1900 average.

[START TABLE 2.4 HERE]

Table 2.4: Observed increase (°C) in GMST and underlying LSAT and SST estimates in various datasets. Numbers in square brackets indicate 5–95% confidence ranges. Trend values are calculated with ordinary least squares following Santer et al. (2008a) and expressed as a total change over the stated period. Datasets considered in this table are those with data for at least 90% of global gridpoints in each year from 1960 onwards. GMST and SST are shown only for data sets which use air temperature (as opposed to climatological SST values) over sea ice. Changes from an 1850–1900 baseline are calculated only for those datasets which have data in at least 80% of years over 1850–1900. GMST values for each year are calculated as the mean of hemispheric means for the NH and SH, while LSAT and SST values are calculated from hemispheric means weighted according to the proportion of land (ocean) in the two hemispheres. This may vary from the methods used by individual data set providers in their own reporting. Products which meet all criteria to be included in the final assessment and contribute to the average are shown in italics. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

To conclude, from 1850–1900 to 1995–2014, GMST increased by 0.85 [0.69 to 0.95] °C, and to the most recent decade (2011–2020) by 1.09 [0.95 to 1.20] °C. Each of the last four decades has in turn been warmer than any decade that preceded it since 1850. Temperatures have increased faster over land than over the oceans since 1850–1900, with warming to 2011–2020 of 1.59 [1.34 to 1.83] °C versus 0.88 [0.68 to 1.01] °C, respectively.

2.3.1.2 Temperatures during the instrumental period – free atmosphere

AR5 reported that it was *virtually certain* that tropospheric temperatures have risen, and stratospheric temperatures fallen, since the mid-20th century, but that assessments of the rate of change and its vertical structure had only *medium confidence* in the NH extratropics and *low confidence* elsewhere. In particular there was *low confidence* in the vertical structure of temperature trends in the upper tropical troposphere.

2.3.1.2.1 Dataset developments

There have been updated radiosonde estimates from the University of Vienna (RAOBCORE and RICH; Haimberger et al., 2012) and a new dataset from the State University of New York (SUNY, (Zhou et al., 2020). There are new versions of AMSU products from the University of Alabama in Huntsville (UAHv6.0; Spencer et al., 2017) and Remote Sensing Systems (RSSv4.0; Mears and Wentz, 2017). These updates have led to convergence in the lower stratosphere layer (Maycock et al., 2018); in particular, the move to UAHv6.0 has addressed homogeneity issues identified by Seidel et al. (2016), although residual differences remain (Christy et al., 2018). Reanalyses products had identified limitations near the 300 hPa level where the contribution of aircraft observations has increased rapidly in recent years (Dee et al., 2011; Gelaro et al., 2017), leading to identified biases (Dee and Uppala, 2009), that have been addressed in ERA5 (Hersbach et al., 2020). Modern reanalyses are generally well aligned with radiosonde and satellite observations in the middle and lower troposphere and lower stratosphere. A new operational mid- and upper-stratospheric dataset (STAR) has been developed by Zou & Qian (2016), merging the previous 1979–2006 SSU dataset (Zou et al., 2014) with a dataset from 1998 onwards drawn from relevant AMSU channels (Wang & Zou, 2014). Further stratospheric satellite-based datasets from various combinations of satellites have been developed by McLandress et al. (2015) and Randel et al. (2016).

New assessments of free-atmosphere temperature are available through radio occultation (RO) and Atmospheric Infrared Sounder (AIRS) products which begin in the early 2000s (Section 1.5.1.1). Global Navigation Satellite System (GNSS)-RO datasets have been compared against AMSU data records, finding almost identical trends (Khaykin et al., 2017). Comparison of RO with collocated radiosondes, Vaisala RS90/92 and GCOS Reference Upper Air Network data (RS92-GDP; Dirksen et al., 2014), show very good correspondence with global annual mean differences of less than 0.2°C in the upper troposphere and lower stratosphere. Radiosonde daytime radiation biases were identified at higher altitudes (Ho et al., 2017; Ladstädter et al., 2015). The stability of RO makes this data a useful comparator for AMSU (Chen & Zou, 2014) and radiosondes (Ho et al., 2017; Tradowsky et al., 2017), as well as anchoring post-2006 reanalyses datasets and improving their consistency in the lower and middle stratosphere (Ho et al., 2020; Long et al., 2017). The effective vertical resolution of RO measurements in the upper troposphere and lower stratosphere was found to be up to 100 m at the tropical tropopause (Zeng et al., 2019a), which is favourable for resolving atmospheric variability (Scherllin-Pirscher et al., 2012; Stocker et al., 2019; Wilhelmsen et al., 2018). Temperature trends in RO products are most consistent with each other and with other observations between 8 km and 25 km (Ho et al., 2012; Steiner et al., 2013, 2020a). The uncertainty increases above 25 km for the early RO period, for which data are based on the single-satellite CHAMP mission, but data at higher altitudes become more reliable for later missions based on advanced receivers (Steiner et al., 2020a), along with the application of corrections for ionospheric effects (Danzer et al., 2020). The uncertainty due to the changing number of observations is reduced by correcting for the sampling uncertainty in RO climatological fields (e.g., Scherllin-Pirscher et al., 2011). For AIRS, thus far, stability of the instrument has been constrained to less than 0.03 °C per decade for selected window channels in a comparison to SSTs measured by ocean buoys (Aumann et al., 2019). Trends were inter-compared with trends in RO data and reanalysis data to assess systematic uncertainties (Leroy et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.3.1.2.2 Assessment of trends

Warming has continued in the lower troposphere according to all radiosonde, reanalyses and satellite datasets, with a rate over 1980–2019 similar to surface warming rates (Table 2.5; c.f. Table 2.4). Radiosonde-based products generally show greater warming rates for 1980–2019 than satellite-based products and reanalyses. They also extend further back to the 1950s and trends since quasi-global coverage around 1960 also show warming (Table 2.5). Trends in RO and AIRS data, supported by radiosonde datasets, exhibit a warming trend in most of the mid- to upper- troposphere at all non-polar latitudes over 2002–2019. These also exhibit faster warming rates in the tropics in the upper troposphere than those observed at or near the surface (Figure 2.12); with the lowermost stratosphere also warming while above it is cooling. There is some spread between different data types in the tropics near the 15 km level, although these differences are reduced to near zero if a subset of radiosonde data, using only high-quality instruments, is used (Steiner et al., 2020b). AMSU tropical middle troposphere data also show that warming rates are near or above those in the lower troposphere, but they are measuring much broader layers which greatly complicates interpretation (Steiner et al., 2020b).

Temperatures averaged through the full lower stratosphere (roughly 10–25 km) have decreased over 1980–2019 in all data products, with the bulk of the decrease prior to 2000. The decrease holds even if the influence of the El Chichon (1982) and Pinatubo (1991) volcanic eruptions on the trend, found by Steiner et al. (2020b) to have increased the 1979–2018 cooling trend by 0.06°C per decade, is removed. Most datasets show no significant or only marginally significant trends over 2000–2019, and the results of Philipona et al. (2018) show weak increases over 2000–2015 in the very lowermost stratosphere sampled by radiosondes.

The STAR dataset shows cooling in the middle and upper stratosphere with a trend of –0.56°C ± 0.16°C per decade for the mid-stratosphere and –0.62°C ± 0.29°C per decade for the upper stratosphere over 1980–2019, although both cooling rates have slowed substantially since the mid-1990s. The overall post-1980 trend is reduced in magnitude by about 0.10°C per decade at both levels if the influences of the El Chichon and Pinatubo eruptions, and the solar cycle, are removed (Zou and Qian, 2016). The results obtained by McLandress et al. (2015) for 1980–2012, Randel et al. (2016) for 1979–2015, and Maycock et al. (2018) for 1979-2016 are broadly consistent with this.

A rise in the tropopause height of 40 to 120 m per decade between 1981 and 2015 was determined from both radiosonde and reanalysis datasets (Xian and Homeyer, 2018). Local studies (e.g. Tang et al., 2017; Chen X. et al., 2019) found stronger trends in some regions near the subtropical jet linked to tropical expansion (Section 2.3.1.4.1). Whilst Seidel and Randel (2006) found that the tropopause height was more closely coupled with temperatures in the stratosphere than those in the troposphere, it is not yet clear whether the rate of increase in tropopause height has experienced a similar recent slowdown to that of the cooling of the lower stratosphere, as short-period trends are typically inconclusive due to significant natural variability (Scherllin-Pirscher et al., 2020). RO data (Gao P. et al., 2015) indicate little change in tropopause height over the short period from 2006 to 2014, but a warming below the tropopause is observed over 2002 to 2019 (Figure 2.12).

In summary, the troposphere has warmed since the mid-20th century. There is *medium confidence* that temperatures in the tropical upper troposphere have warmed faster than those at the surface since 2001, but *low confidence* in changes prior to 2001. It is *virtually certain* that the lower stratosphere has cooled since the mid-20th century. However, most datasets show that lower stratospheric temperatures have stabilized since the mid-1990s with no significant change over the last 20 years. It is *likely* that middle and upper stratospheric temperatures have decreased since 1980, but there is *low confidence* in the magnitude. It is *virtually certain* that the tropopause height has risen over 1980–2019 but there is *low confidence* in the magnitude of this rise, or whether the rate of change has reduced commensurate with stabilized lower stratospheric temperatures.

2.3.1.3 Global hydrological cycle

This section focuses on large-scale changes in a subset of components of the hydrological cycle (Cross-Chapter Box 2.2). Chapter 8 undertakes a holistic assessment of changes in the hydrological cycle integrating observations, modelling and theoretical understanding, while Chapter 11 assesses hydrological cycle extremes such as droughts and floods.

2.3.1.3.1 Paleo perspective of the global hydrological cycle

AR5 assessed large-scale indicators of terrestrial paleo hydroclimate, including as part of its assessment of paleo floods and droughts, but did not assess proxy evidence for paleo hydroclimate indicators over continental and larger scales. The paleoclimate evidence assessed in AR5 was broadly consistent with global hydroclimate scaling with temperature: warmer periods were wetter (e.g., the Pliocene; increased precipitation) with colder periods being drier (e.g., the LGM; decreased precipitation).

Substantial limitations exist in reconstructing the global hydrological cycle prior to the Quaternary, particularly during the Eocene, due to the lack of high-resolution proxy records and their sparsity. Spatial heterogeneity complicates identification of wetting and drying signals during the PETM and the EECO, with paleo data and model simulations suggesting an intensified global hydrological cycle (Carmichael et al., 2016, 2017; Hyland et al., 2017; West et al., 2020), in particular an increased specific humidity (Winnick et al., 2015; van Dijk et al., 2020). Conditions wetter than present were inferred for the MPWP (Cross Chapter Box 2.4), with intensified Asian monsoons (An et al., 2015) and with nevertheless drier conditions over tropical and subtropical SH locations (Pontes et al., 2020). A new global reconstruction of hydroclimate proxies for the LIG points to stronger boreal precipitation compared to 1850–1900 over high latitudes and especially over monsoon areas, with a more heterogeneous signal for the SH (Scussolini et al., 2019). This heterogeneity is also present in the tropics, characterized by large zonal differences in precipitation change due to the variations in the intensity of Walker circulation (section 2.3.1.4.1). Available records indicate reduced global vegetation cover and abundant atmospheric dust deposition during the LGM (increased aridity), particularly over the tropics and high latitudes (Lamy et al., 2014; Újvári et al., 2017). This agrees with models and moisture-sensitive proxies, suggesting an overall decrease in global precipitation during the LGM relative to recent decades, albeit with regional-scale heterogeneity (Cao et al., 2019). Despite lower global precipitation amounts, research since AR5 has identified a wetting of mid-latitudes during the LGM (Putnam and Broecker, 2017; Lowry and Morrill, 2018; Morrill et al., 2018), thereby complicating the characterization of the LGM as a relatively "dry" period. Low evaporation rates and increased top-soil moisture during the LGM may have contributed to elevated levels of large closed-basin lakes located in the 30°–45° latitudinal belts (Putnam and Broecker, 2017; Scheff et al., 2017), such as the southwest US (e.g. Ibarra et al., 2018), southern Australia (Fitzsimmons et al., 2015; Petherick et al., 2013; Sniderman et al., 2019) and Patagonia (e.g. Quade & Kaplan, 2017).

New analyses suggest that during the Holocene, the NH mid-latitudes became increasingly wet, in phase with the strength of the latitudinal temperature and insolation gradients (Shuman and Marsicek, 2016; Routson et al., 2019). Nevertheless, there was also considerable spatial heterogeneity and variability on centennial to millennial timescales (Liefert & Shuman, 2020; Newby et al., 2014; Shuman & Marsicek, 2016; Zhang H. et al., 2018). The NH tropics and many regions of the SH deep tropics experienced wetting up until the early to mid-Holocene but drying thereafter (Muñoz et al., 2017; Nash et al., 2016; Quade et al., 2018; Shanahan et al., 2015). *Evidence* for the SH is *limited*, with a wetting trend during the Holocene in low latitudes of South America (Kanner et al., 2013; Mollier-Vogel et al., 2013) and parts of the African tropics (Schefuß et al., 2011; Chevalier and Chase, 2015) but a drying tendency over southern Australia and New

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Zealand (Barr et al., 2019; van den Bos et al., 2018) and South America (Moreno et al., 2018; Quade & Kaplan, 2017).

For the CE, new proxy records have led to the creation of continental drought atlases (Cook et al., 2015; Morales et al., 2020; Palmer et al., 2015; Stahle et al., 2016) and millennial reanalyses (Steiger et al., 2018; Tardif et al., 2019). These reconstructions highlighted the occurrence of multi-decadal regional mega-droughts in the NH before 1600 CE, particularly during 800–1200 CE, with a predominance of wet periods after 1700 CE (Cook et al., 2015; Rodysill et al., 2018; Shuman et al., 2018). In the SH, much of South America and the African tropics experienced a reduction of precipitation during 900–1200 CE and a wetting peak during 1500–1800 CE (Campos et al., 2019; Fletcher et al., 2018; Lüning et al., 2018; Nash et al., 2016; Tierney et al., 2015), with an opposite pattern in southern subtropical Africa (Lüning et al., 2018; Woodborne et al., 2015). Large multidecadal variability was documented over Australia and New Zealand during the 800–1300 CE period, followed by a well-defined wet period during 1500–1800 CE (Barr et al., 2014; Evans et al, 2019).

To summarise, since AR5 there has been considerable progress in detecting the variations of the global hydrological cycle prior to the instrumental period. There are indications from multiple sources of a wetting trend during the Holocene, particularly for the NH and parts of the SH tropics (*medium confidence*). Hydroclimate during the CE is dominated by regional variability, generally precluding definitive statements on changes at continental and larger scales, with a general reduction of mega-drought occurrences over the last about 500 years (*medium confidence*). Availability of proxy data for assessing Holocene hydroclimate variability is biased towards the NH, with *medium evidence* but *low agreement* for the assessment of SH changes.

2.3.1.3.2 Surface humidity

AR5 reported *very likely* widespread increases in near-surface air specific humidity since the 1970s, abating from around 2000 to 2012 (*medium confidence*). This abatement resulted in a recent decline in relative humidity over the land.

Near surface humidity has been monitored using in situ data (e.g. NOCSv2.0; Berry and Kent, 2011), satellite-derived estimations (e.g. HOAPS3, Liman et al., 2018; J-OFURO3, Tomita et al., 2019), global gridded products such as HadISDH (Willett et al., 2014; 2020), and reanalyses (e.g. ERA5, JRA-55 and 20CRv3). In situ based humidity products suffer from uncertainties over poorly sampled regions particularly in the SH (Berry & Kent, 2011; Kent et al., 2014; Willett et al., 2014). There is general consensus in the inter-annual variability and sign of trends implying *high confidence* in increasing specific humidity since the 1970s and decreasing relative humidity since 2000, particularly over land (Simmons et al., 2010; Willett et al., 2014; 2020). Since 2012, specific humidity over land and ocean has remained well above the 1973–2019 average and reached record or near-record values (Figure 2.13b), with the strong 2015–2016 El Niño event boosting surface moisture levels (Byrne and O'Gorman, 2018). The abatement from around 2000 to 2012 reported in AR5 has not persisted. This is consistent with increases in total column water vapour (Section 2.3.1.3.3) and a resumption of rapid warming in surface temperatures (Section 2.3.1.1.3). The global averaged relative humidity however has remained depressed since 2000 (Figure 2.13d) (Dunn et al., 2017; Simmons et al., 2010; Vicente-Serrano et al., 2018; Willett et al., 2014; 2020).

Since 1973, increases in specific humidity have been widespread and significant across the majority of the land and ocean regions where observations are available (Figure 2.13a). In contrast, trends in relative humidity show distinct spatial patterns with generally increasing trends over the higher latitudes and the tropics and generally decreasing trends over the sub-tropics and mid-latitudes, particularly over land areas (Figure 2.13c). Near-surface specific humidity over the oceans has increased since the 1970s according to several in situ, satellite and reanalysis data records (Kent et al., 2014; Robertson et al., 2020; Willett et al., 2020). According to the HadISDH product, increases in specific humidity and decreases in relative humidity are significant particularly over the NH mid-latitudes (Figure 2.13a,c). Poor data coverage over the SH south of 20°S does not allow for the robust assessment of trends. Sources of uncertainty include the initial measurement accuracy, homogenisation over land, observational height at ships and instrument bias

ACCEPTED VERSION SUBJECT TO FINAL EDITS

adjustment over ocean, and sparse spatio-temporal sampling (Prytherch et al., 2015; Roberts et al., 2019; Willett et al., 2020).

In summary, observations since the 1970s show a *very likely* increase in near surface specific humidity over both land and oceans. A *very likely* decrease in relative humidity has occurred over much of the global land area since 2000, particularly over mid-latitude regions of the NH, with increases at northern high latitudes.

[START FIGURE 2.13 HERE]

Figure 2.13: Changes in surface humidity. (a) Trends in surface specific humidity over 1973–2019. Trends are calculated using OLS regression with significance assessed following AR(1) adjustment after Santer et al (2008a) ('x' marks denote non-significant trends). (b) Global average surface specific humidity annual anomalies (1981–2010 base period). (c) as (a) but for the relative humidity. (d) as (b) but for the global average surface relative humidity annual anomalies. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.13 HERE]

2.3.1.3.3 Total column water vapour

AR5 concluded that total column water vapour (TCWV) *very likely* increased since the 1970s, at a rate that was overall consistent with the Clausius-Clapeyron relationship (about 7% per °C) given the observed increase in atmospheric temperature.

Records prior to the instigation of quasi-global coverage by radiosondes require the use of statistical relationships to infer TCWV from historical SST observations or the evaluation of centennial-scale reanalysis products (Smith and Arkin, 2015). These approaches reveal two periods of positive trends, one during 1910–1940 and the other from 1975 onwards (Zhang et al., 2013; Mieruch et al., 2014; Shi et al., 2018), concurrent with periods of positive SST trends (Figure 2.11). Potential sources of errors in the SST-based estimation of TCWV include both uncertainties in historical SST and uncertainties in the parameters that define the relationship between the variables (Smith & Arkin, 2015). Trends based on 20CRv2c, ERA-20C and ERA-20CM indicate an increase in TCWV over much of the global ocean since the beginning of the 20th century, particularly over the tropics (Bordi et al., 2015; Poli et al., 2016; Smith & Arkin, 2015). TCWV trends estimated since the middle of the 20th century from radiosonde observations show significant increases over North America and large portions of Eurasia, while decreases are restricted to Australia, Eastern Asia and the Mediterranean region (Zhang Y. et al., 2018). Overall, there is a significant increase in TCWV over global land areas since 1979 (Chen & Liu, 2016).

Since the late 1970s a range of satellite missions permit a quasi-global assessment of TCWV. Several satellite products provide water vapour retrievals based upon distinct spectral domains, in addition to products from radiosondes, reanalyses and GNSS radio occultation. The GEWEX Water Vapour Assessment (G-VAP) provided an intercomparison of several TCWV data records, with global coverage but limited timespan (Schröder et al., 2018). The various global products generally exhibit a positive trend since 1979 (Figure 2.14) (Allan et al., 2014; Mieruch et al., 2014; Schröder et al., 2016; Wang X.L. et al., 2016a), most evident over the tropics (Chen & Liu, 2016; Gu & Adler, 2013; Mears et al., 2018; Salamalikis et al., 2021; Wang R. & Liu, 2020). The existence of apparent breakpoints in several products, which are generally coincident with changes in the observing system, lead to trend estimates that are not in line with theoretical expectations imposed by the Clausius-Clapeyron relationship (Schröder et al., 2019a), although other factors such as regional moisture divergence/convergence could account for the observed TCWV-temperature scaling. Substantial potential inhomogeneities affect trend estimates based on satellite, reanalysis and merged products in particular over Central Africa, the Sahara and central South America (Schröder et al., 2016, 2019; Wang et al., X.L. 2016). Moreover, data gaps in observations from ground-based GNSS receivers and radiosondes lead to *low confidence* in TCWV estimation in these regions.

[END FIGURE 2.14 HERE]

In summary, positive trends in global total column water vapour are *very likely* since 1979 when globally representative direct observations began, although uncertainties associated with changes in the observing system imply *medium confidence* in estimation of the trend magnitudes. *Low confidence* in longer-term trends arises from uncertainties in the SST-TCWV relationship and current centennial scale reanalyses, particularly during the first half of the 20th century.

2.3.1.3.4 Global precipitation

AR5 concluded that there was *low confidence* in precipitation change averaged over global land areas prior to 1950, and *medium confidence* thereafter with no significant global trends. There was a *likely* overall increase in precipitation in the well-sampled NH mid-latitudes, with *high confidence* after 1951.

In situ precipitation records over land extend back for centuries in a few locations, and to the early to mid-20th century quasi-globally. Datasets differ in their input data, completeness of records, period covered, and the gridding procedures which, given spatial clustering and the small spatial scales of precipitation, results in differences in global and regional estimates of precipitation changes (Nogueira, 2020; Sun Q. et al., 2018). The spatial variability of observed long-term trends (1901–2019) based on GPCC V2020 and CRU TS 4.04 (Figure 2.15a,b) indicates significant increases in precipitation mainly over eastern North America, northern Eurasia, southern South America and northwestern Australia. Decreases are strongest across tropical western and equatorial Africa and southern Asia. The temporal evolution of global annual land precipitation anomalies exhibits little consistency between GPCC V2020, CRU TS 4.04 and GHCNv4 datasets, especially prior to 1950, that is associated with limitations in data coverage (Figure 2.15c, (Gu & Adler, 2015; Shen et al., 2014; Wu et al., 2013). These disagreements between datasets prior to the 1950s result in differences in trend estimates over global land (Table 2.6). A qualitative consistency in decadal and interdecadal variations between the products is only observed since the 1950s, with primarily positive land precipitation anomalies during the 1950s, 1970s and after the 2000s (Figure 2.15c).

Several satellite-based precipitation datasets improve the representation of the spatio-temporal changes since the late 20th century. Some of these are based exclusively on satellite data (e.g. CMORPH, Joyce et al., 2004; GSMaP, Okamoto et al., 2005), with others being combinations of in situ observations, reanalyses and satellite retrievals (e.g. CMAP, Xie and Arkin, 1997; TRMM 3B43 V7, Huffman et al., 2007; PERSIANN-CDR, Ashouri et al., 2015; CHIRPS, Funk et al., 2015; GPCP V2.3, Adler et al., 2018). These can be affected by systematic and random uncertainties due to inhomogeneities in the satellite-derived precipitation and station data and the uncertainties of blending algorithms (Hegerl et al., 2015; Sun et al., 2018a). The spatial coverage of these products is near-global, with available estimations formally covering 60°S–60°N with decreasing quality from low to high latitudes, depending on the sensors and algorithms used (Hu Q. et al., 2019). A detailed description of the most relevant satellite products is provided in section 10.2.1.1.

Recent trends (1980–2019) for GPCC V2020, CRU TS 4.04 and GPCP V2.3 show significant increases in land precipitation over tropical Africa, the eastern portions of Europe and North America, central Asia and the Maritime Continent (Figure 2.14, d, e and f). Significant decreases are observed over central South America, western North America, northern Africa and the Middle East. A detailed assessment of the recent regional precipitation trends using the same datasets can be found in the Atlas. Global trends for 1980–2019 show a general increase in annual precipitation over land, which is particularly marked for CRU TS 4.04 and GHCNv4 (Table 2.6). These changes have been accompanied by a strengthening of precipitation seasonality over tropical land areas, although with broad spread between different satellite-based (GPCP, MSWEP_V1.2, PERSIANN-CDR) and in situ gridded datasets (GPCC, CRU TS) (Chou et al., 2013; Li X.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

et al., 2016; Tan et al., 2020). Increasing trends since 1980, in contrast to longer-term declining trends since 1901, are particularly evident over much of Africa, while more widespread negative trends were observed over much of southern South America in the more recent period (Knutson and Zeng, 2018) (Atlas 7.2). A faster recent increase in precipitation over global land is inferred comparing the precipitation trends over 1960–2019 with 1980–2019 (Table 2.6). Over the global ocean, the comparison between precipitation datasets is compromised by the different measurement periods, as well as the spatial coverage of the available products (Adler et al., 2017; Jaber & Abu-Allaban, 2020; Nguyen et al., 2018; Nogueira, 2020), limiting the ability to assess the sign and magnitude of precipitation trends. The GPCPv2.3 database (Adler et al., 2017, 2018) exhibits an increase of 2.94 mm yr^{-1} per decade over 1980–2019, principally due to the trends over the Indian ocean and in the tropical western Pacific (Figure 2.15f). The regional patterns of recent trends are consistent with the documented increase in precipitation over tropical wet regions and the decrease over dry areas, estimated through GPCP v2.2 data (Kao et al., 2017; Liu & Allan, 2013; Polson & Hegerl, 2017; Trammell et al., 2015).

[START FIGURE 2.15 HERE]

Figure 2.15: Changes in observed precipitation. (a, b) Spatial variability of observed precipitation trends over land for 1901–2019 for two global in-situ products. Trends are calculated using OLS regression with significance assessed following AR(1) adjustment after Santer et al (2008a) ('x' marks denote non-significant trends). (c) Annual time series and decadal means from 1891 to date relative to a 1981–2010 climatology (note that different products commence at distinct times). (d, e) as (a, b), but for the periods starting in 1980. (f) is for the same period for the globally complete merged GPCP v2.3 product. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[START TABLE 2.6 HERE]

Table 2.6: Globally averaged trend estimates over land and 90% confidence intervals for annual precipitation for each time series in Figure 2.15(c) over three periods all ending in 2019. Trends are calculated using OLS regression with significance assessed after Santer et al (2008a). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

Dataset	Trends in annual precipitation (mm yr^{-1} per decade)		
	1901-2019	**1960-2019**	**1980-2019**
GPCCv2020	1.01* ± 0.99	1.67 ± 3.23	5.60 ± 6.38
CRU TS 4.04	0.57 ± 2.08	0.17 ± 3.12	5.75* ± 5.09
GHCNv4	3.19*± 1.48	5.03* ± 4.87	11.06* ± 9.17
GPCPv2.3			5.41* ± 5.20

* Trend values significant at the 10% level.

[END TABLE 2.6 HERE]

In summary, globally averaged land precipitation has *likely* increased since the middle of the 20th century (*medium confidence*), with *low confidence* in trends prior to 1950. A faster increase in global land precipitation was observed since the 1980s (*medium confidence*), with large interannual variability and regional heterogeneity. Over the global ocean there is *low confidence* in the estimates of precipitation trends, linked to uncertainties in satellite retrievals, merging procedures and limited in situ observations.

2.3.1.3.5 Precipitation minus Evaporation

AR5 concluded that the pattern of precipitation minus evaporation (P-E) over the ocean had been enhanced since the 1950s (*medium confidence*). Saline surface waters had become saltier, while the relatively fresh

ACCEPTED VERSION SUBJECT TO FINAL EDITS

surface waters had become fresher. The inferred changes in P-E were consistent with the observed increased TCWV, although uncertainties in the available products prevented identifying robust trends.

Estimating global-scale trends in P-E using direct observations alone is challenging due to limited evaporation measurements and inhomogeneities in satellite-derived precipitation and evaporation datasets (Hegerl et al., 2015; López et al., 2017). Hence, the assessment of global P-E trends is generally performed using reanalyses, although changes in the observing system imply considerable uncertainty (Skliris et al., 2014a). Since the second half of the 20th century, several reanalyses and observational datasets have shown increases in P-E over global land, although 75% of land areas exhibit no significant changes and both internal variability and observational uncertainty are substantial (Greve et al., 2014; Robertson et al., 2016). The recently released ERA5 (Hersbach et al., 2020) showed improvements in the representation of tropical precipitation, although it overestimates global precipitation trends in comparison to ERA-Interim and GPCP (Nogueira, 2020), and suffers from temporal changes in the annual balance between precipitation and evaporation (Hersbach et al., 2020). The spatial pattern of P-E trends over 1980–2019 (Figure 2.16a) are largely consistent with the trends in the GPCP v2.3 precipitation dataset (Figure 2.15f, Section 2.3.1.3.4) and agrees in sign with the trends from other reanalyses such as JRA-55 and MERRA-2 (Yu L. et al., 2020).

A variety of reanalysis products exhibit diverse temporal evolutions of P-E (Figure 2.16b-d). Globally MERRA-2, ERA20C and ERA20CM exhibit little change whereas JRA-55, ERA5 and 20CRv3 all imply long-term changes (Figure 2.16d). A potential limitation in estimating P-E from some reanalysis products is readily apparent when considering the temporal evolution of global P-E from CFSR and MERRA (Figure 2.16d) which both exhibit strong discontinuities over the global ocean in the late 1990s. Over global land as a whole, precipitation exceeds evaporation (P-E > 0) for all the reanalysis products (Figure 2.16c), with decreasing trends in P-E for ERA5 and JRA-55 and increasing trends for MERRA-2 and CFSR. The P-E over the global ocean is negative (evaporation exceeding precipitation) for most reanalyses (Figure 2.16d), with declining trends in ERA5 and MERRA-2 dominated by trends in evaporation (Bosilovich et al., 2017; Hersbach et al., 2020) (Figure 2.16d). The recent increase in ocean evaporation was also documented for several reanalyses (Craig et al., 2017) and in satellite data (Andersson et al., 2011; Robertson et al., 2014), although with considerable differences between available estimates (Chandanpurkar et al., 2017, Yu L. et al., 2020). An alternative indirect approach to estimate P-E changes is based on near-surface ocean salinity (Section 2.3.3.2), which is partially driven by the freshwater flux at the ocean surface. The near-surface salinity trends are more spatially coherent compared to those revealed by P-E estimates from reanalyses, with an intensification of the water cycle over oceans, especially in subtropical regions (Yu L. et al., 2020, Durack et al., 2012; Skliris et al., 2014). However, the precise rate of water cycle intensification implied by salinity trends is sensitive to methodological choices (e.g., Skliris et al., 2016; Zika et al., 2018).

[START FIGURE 2.16 HERE]

Figure 2.16: Changes in precipitation minus evaporation. (a) Trends in precipitation minus evaporation (P-E) between 1980 and 2019. Trends are calculated using OLS regression with significance assessed following AR(1) adjustment after (Santer et al., 2008; 'x' marks denote non-significant trends). Time series of (b) global, (c) land-only and (d) ocean-only average annual P-E (mm/day). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.16 HERE]

In conclusion, observational uncertainty yields *low confidence* in globally averaged trends in P-E over the 20th century, with a spatial pattern dominated by precipitation changes over land and by evaporation increases over the ocean. Different reanalyses disagree on the sign of long-term changes in the global mean P-E.

2.3.1.3.6 Streamflow

AR5 concluded that there was *low confidence* in a positive trend in global river discharge during the 20th

ACCEPTED VERSION SUBJECT TO FINAL EDITS

century. It noted that many of the largest rivers with long term streamflow records have been impacted by non-climatic human influences such as dam construction or land-use change.

River discharge is monitored widely, although gaps remain at a subcontinental scale over central Asia and Africa (Wei et al., 2020). Substantial recent efforts have been made to generate new global streamflow datasets, consolidating observations from many stream gauges to create streamflow indices (Do et al., 2018; Gudmundsson et al., 2018) and gridded products using neural networks (Barbarossa et al., 2018) or combinations between observations and reanalyses (Suzuki et al., 2018; Ghiggi et al., 2019).

Human intervention on river discharge linked to increases in evapotranspiration and some reduction of intra-annual streamflow variability (Jaramillo and Destouni, 2015, Chai et al., 2020) might affect the detection of trends in extreme daily streamflow events (Do et al., 2017; Gudmundsson et al., 2019). However, these activities have a minor impact on annual streamflow compared to climate variations (Dai et al., 2009; Alkama et al., 2013). Available global studies post-1950 generally concur that there have been more rivers experiencing decreases than increases in runoff (Do et al., 2017; Gudmundsson et al., 2019; X. Shi et al., 2019; Su et al., 2018). Most of the rivers have not experienced statistically significant changes in streamflow, and when globally aggregated there is no significant change (Dai and Zhao, 2017). Global streamflow variability is strongly modulated by ENSO and PDV, with below-normal global streamflow as a response to El Niño events and vice-versa during La Niña episodes (Dai, 2016; Kim, 2019; Liang et al., 2016). The response of streamflow to changes in precipitation associated with ENSO and PDV has heterogeneous regional patterns at subcontinental scales (Section 8.3.2.9.1). No significant trends are found for reanalysis-based discharge estimates over 1993 to 2015 (Chandanpurkar et al., 2017). Uncertainties in global streamflow trends arise predominantly from changes in instrumentation, gauge restoration, recalibration of rating curves, flow regulation or channel engineering (Alkama et al., 2011; Gudmundsson et al., 2018; Ghiggi et al., 2019).

In summary, the sign of global streamflow trends remains uncertain, with slightly more globally gauged rivers experiencing significantly decreasing flows than significantly increasing flows since the 1950s (*low confidence*).

2.3.1.4 Atmospheric circulation

This section focuses on large-scale changes in a subset of components of the atmospheric circulation (Cross-Chapter Box 2.2). Chapter 8 assesses large-scale as well as regional aspects of circulation components and their impact on the hydrological cycle, while Chapter 11 assesses the association of circulation changes and variability with extreme events.

2.3.1.4.1 The Hadley and Walker circulations

AR5 reported *low confidence* in trends in the strength of the Hadley circulation (HC) and the Walker circulation (WC) due to uncertainties in available reanalysis datasets and the large interannual-to-decadal variability of associated circulation patterns. However, AR5 indicated a *likely* widening of the tropical belt since the 1970s, albeit with large uncertainty in the magnitude of this change. There was *high confidence* that the post-1990s strengthening trends of the Pacific WC reversed its weakening observed from the mid-19th century to the 1990s.

Paleo reconstructions of rainfall and trade winds extending over the last 100 kyr show an intensification of the NH HC concurrently with a weakening of the SH HC and a southward shift of the inter tropical convergence zone (ITCZ) during Heinrich stadials (Deplazes et al., 2013; McGee et al., 2018; Stríkis et al., 2018; Wendt et al., 2019). An intensification of the HC associated with conditions similar to La Niña (northward migrations of both the ITCZ and the SH westerlies) was found in reconstructions for the MH (McGee et al., 2014; Mollier-Vogel et al., 2019). Changes in insolation from the mid to late Holocene favoured a southward migration in the position of the ITCZ and the descending branch of the HC in the NH, approaching its current width and position (Wirth et al., 2013a; Thatcher et al., 2020). Tree ring chronologies

ACCEPTED VERSION SUBJECT TO FINAL EDITS

from the NH mid-latitudes over the last 800 years show that the northern edge of the HC tended to migrate southward during positive phases of ENSO and PDV, with northward shifts during negative phases (Alfaro-Sánchez et al., 2018). Between 1400 and 1850 CE the HC over both hemispheres and the ITCZ were displaced southward, consistent with occurrence of drought conditions in several NH regions (Alfaro-Sánchez et al., 2018; Burn and Palmer, 2014; Flores-Aqueveque et al., 2020; Lechleitner et al., 2017; Wirth et al., 2013). Moreover, several proxy records showed not only inter-hemispheric shifts in the ITCZ but a contraction of the tropical belt during 1400–1850 CE, which followed an expansion during 950–1250 CE (Denniston et al., 2016; Griffiths et al., 2016).

From centennial-scale reanalyses, Liu et al. (2012) and D'Agostino and Lionello (2017) found divergent results on HC extent over the last 150 years, although with unanimity upon an intensification of the SH HC. A substantial discrepancy between HC characteristics in centennial-scale reanalyses and in ERA-Interim (D'Agostino and Lionello, 2017) since 1979 yields significant questions regarding their ability to capture changes in HC behaviour. Taken together with the existence of apparent non-climatic artefacts in the dataset (Nguyen et al., 2015), this implies *low confidence* in changes in the extent and intensity of HC derived from centennial-scale reanalyses. However, using multiple observational datasets and centennial-scale reanalyses, Bronnimann et al. (2015) identified a southward shift in the NH HC edge from 1945 to 1980 of about 0.25° latitude per decade, consistent with observed changes in global land monsoon precipitation (Section 2.3.1.4.2).

Since AR5 several studies based upon a range of metrics and different reanalyses products have suggested that the annual mean HC extent has shifted poleward at an approximate rate of 0.1°–0.5° latitude per decade over the last about 40 years (Allen & Kovilakam, 2017; Davis & Birner, 2017; Grise et al., 2018; Staten et al., 2020; Staten et al., 2018; Studholme & Gulev, 2018; Grise & Davis, 2020). The observed widening of the annual mean HC, revealed by a variety of metrics, is primarily due to poleward shift of the NH HC. There have been stronger upward trends in the NH extent of HC after 1992 (Figure 2.17a). The estimated magnitude of the recent changes based on modern-era reanalyses is not as large as that in AR5, due to apparent biases in older-generation reanalyses (Grise et al., 2019). Moreover, large interannual variability leads to uncertainties in estimates of long-term changes (Nguyen et al., 2013, Garfinkel et al., 2015b; Seviour et al., 2018; Staten et al., 2018), particularly for the NH given its zonal asymmetries (Staten et al., 2020; Wang et al., 2020). These large-scale features of the HC based on reanalyses agree with estimates revealed from the Integrated Global Radiosonde Archive (IGRA) during 1979–2012 (Lucas & Nguyen, 2015; Mathew et al., 2016). Recent trends based on reanalyses indicate a larger seasonal widening in the HC for summer and autumn in each hemisphere, although the magnitude of changes in HC extent is strongly dependent on dataset and metrics used (Grise et al., 2018; Hu Y. et al., 2018; Staten et al., 2018). The shifts in the HC position were accompanied by a narrowing ITCZ over the Atlantic and Pacific basins, with no significant change in its location and increases in the precipitation intensity (Byrne et al., 2018).

Trends in the HC intensity since 1979 differ between reanalyses, although there is a tendency toward HC intensification (Figure 2.17b) (Nguyen et al., 2013; Chen et al., 2014; D'Agostino and Lionello, 2017; Huang et al., 2019), which is more marked in the NH than the SH (Studholme and Gulev, 2018). However, the ability of reanalyses to represent the HC strength has been questioned due to inaccurate representation of latent heating distribution, which is directly related to tropical convection and influences the HC dynamics (Chemke and Polvani, 2019; Mathew and Kumar, 2019).

[START FIGURE 2.17 HERE]

Figure 2.17: Timeseries of the annual mean Northern Hemisphere (NH, top curves) and Southern Hemisphere (SH, bottom curves) Hadley Cell extent (a) and Hadley Cell intensity (b) since 1979. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.17 HERE]

Paleo evidence during the LGM indicates a weaker WC over the Indian Ocean (Windler et al., 2019,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

DiNezio et al., 2018), with a stronger Pacific WC (DiNezio and Tierney, 2013). During the Holocene, a transition from a strong WC located more westward during the Early-to-Mid Holocene towards a weak and eastward shifted WC during the late Holocene was inferred from proxy records from the Pacific Warm Pool and South-eastern Asia (Barr et al., 2019; Dang et al., 2020; Griffiths et al., 2020), in concurrence with changes in ENSO activity (section 2.4.2). Reconstructions for the CE showed weakened WC during 1000–1250 and since 1850, with an intensified circulation during 1500–1850 CE (Deng et al., 2017; Xu et al., 2016).

Considering instrumental records, there is considerable interdecadal variability in the strength of the WC, resulting in time-period dependent magnitude and even sign of trends (Bordbar et al., 2017; Carilli et al., 2015; Hou et al., 2018), with some studies reporting weakening over the 20th century (e.g. Liu et al., 2019; Power and Kociuba, 2011), while others reported strengthening (Li Z. et al., 2020), particularly over the last 30-40 years (e.g. Hu et al., 2013; L'Heureux et al., 2013, Yim et al., 2017). Based on estimation of changes in mid-tropospheric velocity from changes in observed cloud cover, Bellomo and Clement (2015) suggest a weakening and eastward shift of the WC over 1920–2010, however the robustness of this signal is questionable due to high uncertainty in the ship reported cloud data records used before 1954. Using centennial-scale 20CR reanalysis Tseng et al. (2019) showed that the vertical westerly wind shear over the western Pacific does not indicate any long-term change during 1900–1980, but shows a marked increase since the 1980s that is not present in ERA-Interim and JRA-55, again calling into question the ability of centennial-scale reanalyses to capture tropical circulation changes. Recent strengthening together with a westward shift of the WC (Bayr et al., 2014; Ma & Zhou, 2016) was identified across several reanalysis products and observational datasets, and using different metrics for quantifying WC. Nevertheless, satellite observations of precipitation and analyses of upper tropospheric humidity suggest substantially weaker strengthening of the WC than implied by reanalyses (Chung et al., 2019). This recent strengthening in the WC is associated with enhanced precipitation in the tropical western Pacific, anomalous westerlies in the upper troposphere, strengthened downwelling in the central and eastern tropical Pacific, and anomalous surface easterlies in the western and central tropical Pacific (Dong and Lu, 2013; Choi et al., 2016, McGregor et al., 2014). Positive trends in sea level pressure over the eastern Pacific and concurrent negative trends over the Indonesian region result in a pattern implying a shift towards a La Niña-like WC regime, with strengthening of the Pacific Trade Winds mainly over 1979–2012 (England et al., 2014; L'Heureux et al., 2013; Sohn et al., 2016; Zhao & Allen, 2019). Seasonal assessment of the WC showed significant changes in the vertical westerly wind shear over the Pacific during the austral summer and autumn implying a strengthening (Clem et al., 2017).

In summary, there has been a *likely* widening of the Hadley circulation since the 1980s, mostly due to its extension in the NH, although there is only *medium confidence* in the extent of the changes. This has been accompanied by a strengthening of the Hadley circulation, particularly in the NH (*medium confidence*). There is *low confidence* in the estimation of long-term trends in the strength of the Walker circulation, which are time period dependent and subject to dataset uncertainties. Trends since 1980 are better characterised and consistent with a *very likely* strengthening that resembles a La Niña-like Walker circulation and a westward shift of the Walker circulation, although with *medium confidence* in the magnitude of the changes, arising from the differences between satellite observations and reanalysis products.

2.3.1.4.2 Global monsoon changes

AR5 reported a weakening of the global monsoon (GM) circulation as well as a decrease of global land monsoon rainfall over the second half of the 20th century. Nevertheless, there was *low confidence* in the observed circulation trends due to uncertainties in reanalysis products and in the definition of the monsoon area. From a paleo perspective, AR5 only assessed regional monsoon changes.

New research based on high-resolution proxies reinforces previous findings on the influence of orbital cycles on GM variability on millennial time scales. The intensity of the monsoon systems is generally out of phase between hemispheres, being associated with the precession cycle (~21–23 kyr) (An et al., 2015; Seth et al., 2019; Wang P.X. et al., 2017), with intensified NH monsoon systems during precession minima (Toucanne et al., 2015; Wagner et al., 2019). The eccentricity forcing (about 100 kyr cycle) shows stronger GM during

ACCEPTED VERSION SUBJECT TO FINAL EDITS

interglacial periods (An et al., 2015; Mohtadi et al., 2016; Wang P. X. et al., 2014; 2017). Changes in obliquity (about 41 kyr cycle) modify the strength of monsoon systems, with increased summer monsoon rainfall when obliquity is maximal (Liu Yi et al., 2015; Mohtadi et al., 2016). Millennial scale variability in GM during the LDT was also linked to the occurrences of Heinrich stadials, resulting in weakened NH monsoons and intensified SH monsoons (An et al., 2015; Margari et al., 2020; Wang P.X. et al., 2017).

An intensification of the NH monsoons in the early to mid-Holocene with increased precipitation and regional expansions of rainfall areas identified through a variety of proxy records is shown by Biasutti et al., (2018) and Wang P.X. et al. (2017). The response for the SH monsoons during this period indicates a weakening in both summer and winter precipitation (Sachs et al., 2018; Wang P.X. et al., 2014; 2017). A decline in GM precipitation and a retraction of the northern fringes of monsoon areas was inferred from the mid-Holocene onwards, with some regions experiencing wetter conditions during the mid to late Holocene compared with present and a strengthening of the SH monsoons (Sachs et al., 2018; Wang P.X. et al., 2014; 2017). For the CE, GM reconstructions exhibit inter-hemispheric contrast during the period 950–1250 CE, with intensified NH monsoons and weakened SH monsoons, and the opposite pattern during 1400–1850 CE (An et al., 2015; Wang P. X. et al., 2014).

Direct observations highlight that the GM land precipitation, particularly over the NH, experienced a slight increase from 1900 through the early 1950s, followed by an overall decrease from the 1950s to the 1980s, and then an increase to present (Huang X. et al., 2019; Kitoh et al., 2013; Wang B. et al., 2018; 2020). This highlights the existence of multidecadal variations in the NH monsoon circulation patterns and precipitation intensity (Monerie et al., 2019; Wang B. et al., 2013; Wang P.X. et al., 2014; 2017). An overall increase in monsoon precipitation during extended boreal summer (JJAS) over the NH since 1979 is revealed by GPCP (Deng et al., 2018; Han et al., 2019) and CMAP for 1980–2010 (Jiang et al. 2016). SH summer monsoon behaviour is dominated by strong interannual variability and large regional differences (Deng et al., 2018; Han et al., 2019; Jiang et al., 2016; Kamae et al., 2017; Kitoh et al., 2013; Lin et al., 2014), with no significant trends reported by GPCP and CMAP (Deng et al., 2018). Uncertainty predominantly arises from the observed increase in tropical precipitation seasonality (Feng et al., 2013) and the estimation of GM precipitation over the ocean areas, leading to a large apparent spread across datasets (Kitoh et al., 2013b; Kamae et al., 2017).

In summary, observed trends during the last century indicate that the GM precipitation decline reported in AR5 has reversed since the 1980s, with a *likely* increase mainly due to a significant positive trend in the NH summer monsoon precipitation (*medium confidence*). However, GM precipitation has exhibited large multi-decadal variability over the last century, creating *low confidence* in the existence of centennial-length trends in the instrumental record. Proxy reconstructions show a *likely* NH monsoons weakening since the mid-Holocene, with opposite behaviour for the SH monsoons.

2.3.1.4.3 Extratropical jets, storm tracks, and blocking

AR5 reported a *likely* poleward shift of storm tracks and jet streams since the 1970s from different datasets, variables and approaches. These trends were consistent with the HC widening and the poleward shifting of the circulation features since the 1970s. There was *low confidence* in any large-scale change in blocking.

Proxy records consistent with modelling results imply a southward shift of the storm tracks over the North Atlantic during the LGM (Raible et al., 2021). A variety of proxies are available for the changes in the position of the extratropical jets / westerlies during the Holocene. Recent syntheses of moisture-sensitive proxy records indicate drier-than-present conditions over mid-latitudes of western North America (Hermann et al., 2018; Liefert and Shuman, 2020) during the MH, which together with a weakened Aleutian Low (Bailey et al., 2018) implies that the winter North Pacific jetstream was shifted northward. A synthesis of lines of evidence from the SH indicates that the westerly winds were stronger over 14–5 ka, followed by regional asymmetry after 5 ka (Fletcher & Moreno, 2012). There is no consensus on the shifts of the SH westerlies with some studies implying poleward migrations (Lamy et al., 2010; Voigt et al., 2015; Turney et al., 2017; Anderson et al., 2018) and others suggesting an equatorward shift (Kaplan et al., 2016) in the MH.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

During 950–1400 CE, hydroclimate indicators suggest a northward shift of Pacific storm tracks over North America (McCabe-Glynn et al., 2013; Steinman et al., 2014) which was comparable in magnitude to that over 1979–2015 (Wang et al., 2017). Storm tracks over the North Atlantic-European sector shifted northward as indicated by multi-proxy indicators over the North Atlantic (Wirth et al., 2013; Orme et al., 2017) and Mediterranean (Roberts et al., 2012). Reconstructed westerly winds in the SH suggest a poleward shift (Goodwin et al., 2014; Koffman et al., 2014; Lamy et al., 2010; Moreno et al., 2018; Schimpf et al., 2011), with latitudinal change comparable to that during recent decades (Swart and Fyfe, 2012; Manney and Hegglin, 2018).

Multiple reanalyses show that since 1979 the subtropical jet wind speeds have generally increased in winter and decreased in summer in both hemispheres, but the trends are regionally dependent (Pena-Ortiz et al., 2013; Manney and Hegglin, 2018; Lee et al., 2019). Over NH mid-latitudes, the summer zonal wind speeds have weakened in the mid-troposphere (Francis and Vavrus, 2012; Coumou et al., 2014, 2015; Haimberger and Mayer, 2017). Meanwhile there are indications of enhanced jetstream meandering in boreal autumn at the hemispheric scale (Francis and Vavrus, 2015; Di Capua and Coumou, 2016), whereas the regional arrangement of meandering depends on the background atmospheric state (Cohen et al., 2020). These meandering trends, however, are sensitive to the metrics used (Cattiaux et al., 2016; Hassanzadeh et al., 2014; Screen & Simmonds, 2013; Vavrus, 2018). Hypothesised links to Arctic warming are assessed in Cross-Chapter Box 10.1.

Multiple reanalyses and radiosonde observations show an increasing number of extratropical cyclones over the NH since the 1950s (Chang & Yau, 2016; Wang X. L. et al., 2016). The positive trends are generally consistent among reanalyses since 1979, though with considerable spread (Tilinina et al., 2013; Wang X. L. et al., 2016). In recent decades the number of deep extratropical cyclones has increased over the SH (Reboita et al., 2015; Wang X. L. et al., 2016) (Section 8.3.2.8.1, Figure 8.12), while the number of deep cyclones has decreased in the NH in both winter and summer (Neu et al., 2013; Wang et al., 2017, Chang et al., 2016; Coumou et al., 2015; Gertler & O'Gorman, 2019). The regional changes for different intensity extratropical cyclones are assessed in Section 8.3.2.8.1. The assessment of trends is complicated by strong interannual-decadal variability, sensitivity to dataset choice and resolution (Tilinina et al., 2013; Lucas et al., 2014; Wang et al., 2016; Pepler et al., 2018; Rohrer et al., 2018) and cyclone identification / tracking methods (Neu et al., 2013; Grieger et al., 2018). Thus there is overall *low confidence* for recent changes in global extratropical storm tracks.

A consistent poleward shift of the tropospheric extratropical jets since 1979 is reported by multiple reanalyses (Davis and Rosenlof, 2012; Davis and Birner, 2013; Pena-Ortiz et al., 2013; Manney and Hegglin, 2018) (Figure 2.18), and radiosonde winds (Allen et al., 2012). This is generally consistent with the earlier reported shifts retrieved from satellite temperature observations (Fu and Lin, 2011; Davis and Rosenlof, 2012). After the 1960s the magnitude of meridional shifts in extratropical jets over both the North Atlantic and North Pacific in August is enhanced compared to multi-century variability (Trouet et al., 2018). Despite some regional differences (Ma & Zhang, 2018; Melamed-Turkish et al., 2018; Norris et al., 2016; Wang J. et al., 2017a; Woollings et al., 2014; Xue & Zhang, 2018), overall poleward deflection of storm tracks in boreal winter over both the North Atlantic and the North Pacific was identified during 1979–2010 (Tilinina et al., 2013). Over the SH extra-tropics there is a similarly robust poleward shift in the polar jet since 1979 (Pena-Ortiz et al., 2013; Manney and Hegglin, 2018; WMO, 2018), although after 2000 the December-January-February (DJF) tendency to poleward shift of the SH jet stream position ceased (Banerjee et al., 2020). The general poleward movement in midlatitude jet streams (Lucas et al., 2014) is consistent with the expansion of the tropical circulation (Section 2.3.1.4.1). The changes of extratropical jets and westerlies are also related to the annular modes of variability (Section 2.4, Annex IV).

Robust trends in blocking have only been found in certain regions and specific seasons during recent decades. Increases in blocking frequency have occurred over low-latitude regions in the North Atlantic in boreal winter (Davini et al., 2012), the South Atlantic in austral summer (Dennison et al., 2016) and the southern Indian Ocean in austral spring (Schemm, 2018). Over the subpolar North Atlantic sustained periods of positive Greenland blocking were identified during 1870–1900 and from the late 1990s to 2015 (Hanna et al., 2015). Further analysis of association of Greenland blocking with the NAM is provided in Section 2.4.1.1. Meanwhile, a reduced blocking frequency has been found over winter in Siberia (Davini et al., 2012)

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and the southwestern Pacific in austral spring (Schemm, 2018). Over Eastern European Russia and Western Siberia (40–100E) a tendency towards longer blocking events was reported by Luo et al. (2016) for 2000–2013 and by Tyrlis et al. (2020) for 1979–2017. Inter-annual variance in the number of blocking events over the SH (Oliveira et al., 2014) and North Atlantic (Kim & Ha, 2015) has enhanced. Blocking events and their trends are sensitive to choice of datasets, calculation periods and methods (Barnes et al., 2014; Cheung et al., 2013; Kononova & Lupo, 2020; Pepler et al., 2018; Rohrer et al., 2018; Woollings et al., 2018b). As a result, hemispheric and global trends in blocking frequency have overall *low confidence.*

In summary, the total number of extratropical cyclones has *likely* increased since the 1980s in the NH (*low confidence*), but with fewer deep cyclones particularly in summer. The number of strong extratropical cyclones has *likely* increased in the SH (*medium confidence*). The extratropical jets and cyclone tracks have *likely* been shifting poleward in both hemispheres since the 1980s with marked seasonality in trends (*medium confidence*). There is *low confidence* in shifting of extratropical jets in the NH during the mid-Holocene and over 950–1400 CE to latitudes that *likely* were similar to those since 1979. There is *low confidence* in observed global-scale changes in the occurrence of blocking events.

[START FIGURE 2.18 HERE]

Figure 2.18: Trends in ERA5 zonal-mean zonal wind speed. Shown are (a) DJF (December-January-February), (b) MAM (March-April-May), (c) JJA (June-July-August) and (d) SON (September-October-November). Climatological zonal winds during the data period are shown in solid contour lines for westerly winds and in dashed lines for easterly. Trends are calculated using OLS regression after Santer et al (2008a) ('x' marks denote non-significant trends). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.18 HERE]

2.3.1.4.4 Surface wind and sea level pressure

AR5 concluded that surface winds over land had generally weakened. The *confidence* for both land and ocean surface wind trends was *low* owing to uncertainties in datasets and measures used. Sea level pressure (SLP) was assessed to have *likely* decreased from 1979–2012 over the tropical Atlantic and increased over large regions of the Pacific and South Atlantic, but trends were sensitive to the period analysed.

Terrestrial in situ wind datasets have been updated and the quality-control procedures have been improved, with particular attention to homogeneity and to better retaining true extreme values (Dunn et al., 2012; 2014; 2016). Global mean land wind speed (excluding Australia) from HadISD for 1979–2018 shows a reduction (stilling) of 0.063 m s^{-1} per decade (Azorin-Molina et al., 2019). Trends are broadly insensitive to the subsets of stations used. Although the meteorological stations are unevenly distributed worldwide and scarce in South America and Africa, the majority exhibit stilling particularly in the NH (Figure 2.19). Regionally, strong decreasing trends are reported in central Asia and North America (–0.106 and –0.084 m s^{-1} per decade respectively) during 1979–2018 (McVicar et al., 2012; Vautard et al., 2012; Wu et al., 2018; Azorin-Molina et al., 2019). This stilling tendency has reversed after 2010 and the global mean surface winds have strengthened (Azorin-Molina et al., 2020; Zeng et al., 2019), although the robustness of this reversal is unclear given the short period and interannual variability (Kousari et al., 2013; Kim and Paik, 2015; Azorin-Molina et al., 2019).

[START FIGURE 2.19 HERE]

Figure 2.19: Trends in surface wind speed. (a) Station observed winds from the integrated surface database (HadISD v2.0.2.2017f); (b) Cross-Calibrated Multi-Platform wind product; (c) ERA5; and (d) wind speed from the Objectively Analyzed Air-Sea Heat Fluxes dataset, release 3. White areas indicate incomplete or missing data. Trends are calculated using OLS regression with significance assessed following AR(1) adjustment after Santer et al (2008c) ('x' marks denote non-significant trends). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

[END FIGURE 2.19 HERE]

Over the ocean, datasets demonstrate considerable disagreement in surface wind speed trends and spatial features (Kent et al., 2013). Global ocean surface winds from NOCv2.0 demonstrate upward trends of about 0.11 m s^{-1} per decade (1979–2015) with somewhat smaller trends from WASwind for 1979–2011 (Azorin-Molina et al., 2017, 2019). The datasets are consistent until 1998, but diverge thereafter. Both ERA5 and JRA-55 reanalyses show consistently increasing global marine wind speeds over 1979–2015, though flattening since 2000, whereas MERRA-2 agrees until 1998, but then exhibits increased variability and an overall decrease in the last two decades (Azorin-Molina et al., 2019). This agrees with estimates by Sharmar et al. (2021) showing upward ocean wind trends from 1979 to 2000 which are consistent in ERA-Interim, ERA5 and MERRA-2, but disagree with CFSR trends for the same period. Over 2000–2019 all reanalyses show diverging tendencies. An updated multiplatform satellite database (comprising data from altimeters, radiometers, and scatterometers) from 1985–2018 shows small increases in mean wind speed over the global ocean, with the largest increase observed in the Southern Ocean (Young & Ribal, 2019), consistent with signals in ERA-Interim, ERA5 and MERRA-2 (Sharmar et al., 2021). Overall, most products suggest positive trends over the Southern Ocean, western North Atlantic and the tropical eastern Pacific since the early 1980s.

The modern era reanalyses exhibit SLP increases over the SH subtropics with stronger increases in austral winter over 1979–2018. Over the NH, SLP increased over the mid-latitude Pacific in boreal winter and decreased over the eastern subtropical and mid-latitude North Atlantic in boreal summer. Discrepancies in the low-frequency variations during the first half of the 20th century exist in the centennial-scale reanalysis products (Befort et al., 2016). Overall, modern reanalysis datasets support the AR5 conclusion that there is no clear signal for trends in the strength and position of the permanent and quasi-permanent pressure centres of action since the 1950s. Instead, they highlight multi-decadal variations. Large-scale SLP is strongly associated with the changes in modes of variability (Section 2.4, Annex IV).

In summary, since the 1970s a worldwide weakening of surface wind has *likely* occurred over land, particularly marked in the NH, with *low confidence* in a recent partial recovery since around 2010. Differences between available wind speed estimates lead to *low confidence* in trends over the global ocean as a whole but with most estimates showing strengthening globally over 1980–2000 and over the last four decades in the Southern Ocean, western North Atlantic and the tropical eastern Pacific.

2.3.1.4.5 Stratospheric polar vortex and sudden warming events

AR5 assessed changes in the polar vortices and reported a *likely* decrease in the lower-stratospheric geopotential heights over Antarctica in spring and summer at least since 1979.

Multiple definitions for the polar vortex strength and sudden stratospheric warming (SSW) events have been proposed and compared (Butler et al., 2015; Palmeiro et al., 2015; Waugh et al., 2017; Butler and Gerber, 2018), and new techniques identifying daily vortex patterns and SSWs have been developed (Kretschmer et al., 2018; Mitchell et al., 2013a). Errors in reanalysis stratospheric winds were assessed and discrepancies in stratospheric atmospheric circulation and temperatures between reanalyses, satellites and radiosondes have been reported (Mitchell et al., 2013a; Duruisseau et al., 2017).

The northern stratospheric polar vortex has varied seasonally and with altitude during recent decades. Multiple reanalysis and radiosonde datasets show that the midwinter lower stratospheric geopotential height (150 hPa) over the polar region north of 60°N has increased significantly since the early 1980s (Bohlinger et al., 2014; Garfinkel et al., 2017). This signal extends to the middle and upper stratosphere. In January-February zonal winds north of 60°N at 10 hPa have been weakening (Kim et al., 2014; Kretschmer et al., 2018). Daily atmospheric circulation patterns over the northern polar stratosphere exhibit a decreasing frequency of strong vortex events and commensurate increase in more-persistent weak events, which largely explains the observed significant weakening of the vortex during 1979–2015 (Kretschmer et al., 2018). The northern polar vortex has weakened in early winter but strengthened during late winter (Bohlinger et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2014; Garfinkel et al., 2015a; 2017; Ivy et al., 2016; Kretschmer et al., 2018; Seviour, 2017). In the middle and upper stratosphere, a strengthening trend of the northern polar vortex during DJF has occurred since 1998, contrasting the weakening trend beforehand (Hu et al., 2018). The position of the polar vortex also has long-term variations, exhibiting a persistent shift toward Northern Siberia and away from North America in February over the period 1979–2015 (Zhang J. et al., 2016, 2018). Multiple measures show similar location changes (Seviour, 2017).

The SSW, a phenomenon of rapid stratospheric air temperature increases (sometimes by more than 50°C in 1–2 days), is tightly associated with the reversal of upper stratospheric zonal winds, and a resulting collapse or substantial weakening of the stratospheric polar vortex (Butler et al., 2015; Butler and Gerber, 2018) and on average occurs approximately 6 times per decade in the NH winter (Charlton et al., 2007; Butler et al., 2015). The SSW record from all modern reanalyses is very consistent. There is a higher occurrence of major midwinter SSWs in the 1980s and 2000s with no SSW events during 1990–1997 (Reichler et al., 2012, Butler et al., 2015). An assessment of multidecadal variability and change in SSW events is sensitive to both chosen metric and methods (Palmeiro et al., 2015). Due to the lack of assimilation of upper air data, the centennial-scale reanalyses do not capture SSW events, even for the most recent decades (Butler et al., 2015, 2017) and hence cannot inform on earlier behaviour. There has been considerably less study of trends in the southern hemispheric stratosphere vortex strength despite the interest in the ozone hole and the *likely* impact of the southern hemispheric stratosphere vortex strength on it. The occurrence of SSW events in the SH is not as frequent as in the NH, with only 3 documented events in the last 40 years (Shen et al., 2020).

In summary, it is *likely* that the northern lower stratospheric vortex has weakened since the 1980s in midwinter, and its location has shifted more frequently toward the Eurasian continent. The short record and substantial decadal variability yields *low confidence* in any trends in the occurrence of SSW events in the NH winter and such events in the SH are rare.

2.3.2 Cryosphere

This section focuses on large-scale changes in a subset of components of the cryosphere (Cross-Chapter Box 2.2). Chapter 9 undertakes a holistic assessment of past and possible future changes at the process level in the cryosphere, including those at regional scales, integrating observations, modelling and theoretical understanding, while, here in chapter 2, the focus is on past large-scale, observation-based cryospheric changes.

2.3.2.1 Sea ice coverage and thickness

2.3.2.1.1 Arctic Sea Ice

AR5 reported that the annual mean Arctic sea ice extent (SIE) *very likely* decreased by 3.5–4.1% per decade between 1979 and 2012 with the summer sea ice minimum (perennial sea ice) *very likely* decreasing by 9.4–13.6% per decade. This was confirmed by SROCC reporting the strongest reductions in September (12.8 ± 2.3% per decade; 1979–2018) and stating that these changes were *likely* unprecedented in at least 1 kyr (*medium confidence*). The spatial extent had decreased in all seasons, with the largest decrease for September (*high confidence*). AR5 reported also that the average winter sea ice thickness within the Arctic Basin had *likely* decreased by between 1.3 m and 2.3 m from 1980 to 2008 (*high confidence*), consistent with the decline in multi-year and perennial ice extent. SROCC stated further that it was *virtually certain* that Arctic sea ice had thinned, concurrent with a shift to younger ice. Lower sea ice volume in 2010–2012 compared to 2003–2008 was documented in AR5 (*medium confidence*). There was *high confidence* that, where the sea ice thickness had decreased, the sea ice drift speed had increased.

Proxy records are used in combination with modelling to assess Arctic paleo sea-ice conditions to the extent possible. For the Pliocene, *limited* proxy *evidence* of a reduced sea-ice cover compared to ‘modern’ winter conditions (Knies et al., 2014; Clotten et al., 2018) and model simulations of a largely ice-free Arctic Ocean during summer (Feng et al., 2019; Howell et al., 2016; Li F. et al., 2020) imply *medium confidence* that the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Arctic Ocean was seasonally ice covered. Over the LIG, sparse proxy reconstructions (Stein et al., 2017; Kremer et al., 2018) and proxy evidence from marine sediment (Kageyama et al., 2021) provide *medium confidence* of perennial sea-ice cover.

Over the past 13 kyr proxy records suggest extensive sea ice coverage during the Younger Dryas (at the end of the LDT), followed by a decrease in sea ice coverage during the Early Holocene, and increasing sea ice coverage from the MH to the mid-1400s (De Vernal et al., 2013; Belt et al., 2015; Cabedo-Sanz et al., 2016; Armand et al., 2017; Belt, 2018). There is *limited evidence* that the Canadian Arctic had less multiyear sea ice during the Early Holocene than today (Spolaor et al., 2016). For more regional details on paleo arctic sea ice see Section 9.3.1.1.

Current pan-Arctic SIE conditions (annual means and late summer) are unprecedented since at least 1850 (Brennan et al., 2020; Walsh et al., 2017; 2019, Figure 2.20a), while, as reported in SROCC, there remains *medium confidence* that the current September (late summer) Arctic sea ice loss is unprecedented during the past 1 kyr. Sea ice charts since 1850 (Walsh et al., 2017; 2019) suggest that there was no significant trend before the 1990s, but the uncertainty of these estimates is large and could mask a trend, a possibility illustrated by Brennan et al. (2020), who found a loss of Arctic sea ice between 1910 and 1940 in an estimate based on a data assimilation approach.

There has been a continuing decline in SIE and Arctic sea ice area (SIA) in recent years (Figure 2.20a). To reduce grid-geometry associated biases and uncertainties (Notz, 2014; Ivanova et al., 2016; Meier and Stewart, 2019) SIA is used in addition to, or instead of SIE herein (see also section 9.3.1). A record-low Arctic SIA since the start of the satellite era (1979) occurred in September 2012 (Figure 2.20a). Decadal SIA means based on the average of three different satellite products decreased from 6.23–3.76 million km^2 for September and 14.52–13.42 million km^2 for March SIA (Figure 2.20a). Initial SIA data for 2020 (OSISAF) are within the range of these recent decadal means or slightly below (Figure 2.20a). SIA has declined since 1979 across the seasonal cycle (Figure 9.13). Most of this decline in SIA has occurred after 2000, and is superimposed by substantial interannual variability. The sharp decline in Arctic summer SIA coincides with earlier surface melt onset (Mortin et al., 2016; Bliss et al., 2017), later freeze-up, and thus a longer ice retreat and open water period (Stammerjohn et al., 2012; Parkinson, 2014; Peng et al., 2018).

[START FIGURE 2.20 HERE]

Figure 2.20: Changes in Arctic and Antarctic sea ice area. (a) Three time series of Arctic sea ice area (SIA) for March and September from 1979 to 2020 (passive microwave satellite era). In addition, the range of SIA from 1850–1978 is indicated by the vertical bar to the left. Decadal means for the three series for the first and most recent decades of observations are shown by horizontal lines in grey (1979–1988) and black (2010–2019). (b): Three time series of Antarctic sea ice area for September and February (1979–2020). Sea ice area values have been calculated from sea ice concentration fields. Available data for 2020 (OSISAF) is shown in both (a) and (b). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.20 HERE]

Over the past two decades, first-year sea ice has become more dominant and the oldest multiyear ice (older than 4 years) which in March 1985 made up 33% of the Arctic sea ice cover, has nearly disappeared, making up 1.2% in March 2019 (Perovich et al., 2020). The loss of older ice is indicative of a thinning overall of ice cover (Tschudi et al., 2016), but also the remaining older ice has become thinner (Hansen E. et al., 2013). Since in situ ice thickness measurements are sparse, information about ice thickness is mainly based on airborne and satellite surveys. Records from a combination of different platforms show for the central and western Arctic Ocean (Arctic Ocean north of Canada and Alaska) negative trends since the mid-1970s (Kwok, 2018; Lindsay & Schweiger, 2015), with a particularly rapid decline during the 2000s, which coincided with a large loss of multiyear sea ice. Direct observations from 2004 and 2017 indicate a decrease

ACCEPTED VERSION SUBJECT TO FINAL EDITS

of modal ice thickness in the Arctic Ocean north of Greenland by 0.75 m, but with little thinning between 2014 and 2017 (Haas et al., 2017). This agrees with data based on satellite altimetry and airborne observations, showing no discernible thickness trend since 2010 (Kwok & Cunningham, 2015; Kwok, 2018; Kwok and Kacimi, 2018) (Figure 2.21). However, sea ice thickness derived from airborne and spaceborne data is still subject to uncertainties imposed by snow loading. For radar altimeters, insufficient penetration of radar signal into the snowpack results in overestimation of ice thickness (e.g., Ricker et al., 2015; King et al., 2018a; Nandan et al., 2020). Negative trends in ice thickness since the 1990s are also reported from the Fram Strait in the Greenland Sea, and north of Svalbard (Hansen E. et al., 2013; King et al., 2018; Renner et al., 2014; Rösel et al., 2018; Spreen et al., 2020). Thickness data collected in the Fram Strait originate from ice exported from the interior of the Arctic Basin and are representative of a larger geographical area upstream in the transpolar drift. A reduction of survival rates of sea ice exported from the Siberian shelves by 15% per decade has interrupted the transpolar drift and affected the long-range transport of sea ice (Krumpen et al., 2019). The thinner and on average younger ice has less resistance to dynamic forcing, resulting in a more dynamic ice cover (Hakkinen et al., 2008; Spreen et al., 2011; Vihma et al., 2012; Kwok et al., 2013).

[START FIGURE 2.21 HERE]

Figure 2.21: Arctic sea ice thickness changes (means) for autumn (red/dotted red) and winter (blue/dotted blue). Shadings (blue and red) show 1 S.E. ranges from the regression analysis of submarine ice thickness and expected uncertainties in satellite ice thickness estimates. Data release area of submarine data ice thickness data is shown in inset. Satellite ice thickness estimates are for the Arctic south of 88°N. Thickness estimates from more localized airborne/ground electromagnetic surveys near the North Pole (diamonds) and from Operation IceBridge (circles) are shown within the context of the larger scale changes in the submarine and satellite records. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.21 HERE]

SROCC noted the lack of continuous records of snow on sea ice. Nevertheless in recent decades, more snow on sea ice has been observed in the Atlantic sector in the Arctic than in the Western Arctic Ocean (Webster et al., 2018). Previously, Warren et al. (1999) showed that over 1954–1991 there were weak trends towards declining snow depth on sea ice in the Pacific sector. Recent observations indicate a substantial thinning of the spring snowpack in the western Arctic (Cavalieri et al., 2012; Brucker and Markus, 2013; Kurtz et al., 2013; Laxon et al., 2013; Webster et al., 2018). In contrast, thick snow over Arctic sea ice in the Atlantic sector north of Svalbard (snow thickness around 0.4 m or more) has been observed in the 1970s and since the 1990s (Rösel et al., 2018), but data are too sparse to detect trends.

In summary, over 1979–2019 Arctic SIA has decreased for all months, with the strongest decrease in summer (*very high confidence*). Decadal means for SIA decreased from the first to the last decade in that period from 6.23 to 3.76 million km^2 for September, and from 14.52 to 13.42 million km^2 for March. Arctic sea ice has become younger, thinner and faster moving (*very high confidence*). Snow thickness on sea ice has decreased in the western Arctic Ocean (*medium confidence*). Since the Younger Dryas at the end of the LDT, proxy indicators show that Arctic sea ice has fluctuated on multiple time scales with a decrease in sea ice coverage during the Early Holocene and an increase from the MH to the mid-1400s. Current pan-Arctic sea ice coverage levels (annual mean and late summer) are unprecedentedly low since 1850 (*high confidence),* and with *medium confidence* for late summer for at least the past 1 kyr.

2.3.2.1.2 Antarctic Sea Ice

AR5 reported a small but significant increase in the total annual mean Antarctic SIE that was *very likely* in the range of 1.2–1.8% per decade between 1979 and 2012 (0.13–0.20 million km^2 per decade) (*very high confidence*), while SROCC reported that total Antarctic sea ice coverage exhibited no significant trend over the period of satellite observations (1979–2018) (*high confidence*). SROCC noted that a significant positive

ACCEPTED VERSION SUBJECT TO FINAL EDITS

trend in mean annual ice cover between 1979 and 2015 had not persisted, due to three consecutive years of below-average ice cover (2016–2018). SROCC stated also that historical Antarctic sea ice data from different sources indicated a decrease in overall Antarctic sea ice cover since the early 1960s, but was too small to be separated from natural variability (*high confidence*).

There is only *limited evidence* from predominantly regional paleo proxies for the evolution of Southern Ocean sea ice before the instrumental record and estimates are not available for all proxy target periods (Section 9.3.2). Proxies from marine sediments for intervals preceding and following the MPWP indicate open water conditions with less sea-ice than modern conditions (Taylor-Silva and Riesselman, 2018; Ishino and Suto, 2020). During the LGM, proxies indicate that summer sea ice coverage reached the polar ocean front (e.g., Nair et al., 2019). More recently, sea ice coverage appears to have fluctuated substantially throughout the Holocene (e.g., for the western Amundsen Sea, Lamping et al., 2020). At the beginning of the CE, regional summer sea ice coverage in the north-western Ross Sea was lower than today (Tesi et al., 2020). Crosta et al. (2021) suggest, based on different proxies, four different phases with 7–10 months periods of sea ice occurrence per year in the Antarctic region off Adelie Land during the CE, where each phase was several hundred years long.

More recent sea ice reconstructions are based on diverse sources including whaling records (De La Mare, 1997, 2009; Cotté and Guinet, 2007), old ship logbooks (Ackley et al., 2003; Edinburgh and Day, 2016), and ice core records (Curran et al., 2003; Abram et al., 2010; Sinclair et al., 2014), amongst other methods (e.g. Murphy et al., 2014). These reconstructions, in combination with recent satellite-based observations indicate: i) a decrease in summer SIE across all Antarctic sectors since the early- to mid-20th century; ii) a decrease in winter SIE in the East Antarctic, and Amundsen-Bellingshausen Seas sectors starting in the 1960s; and iii) small fluctuations in winter SIE in the Weddell Sea over the 20th century (Hobbs et al., 2016a,b). There are also ice-core indications that the pronounced Ross Sea increase dates back to the mid-1960s (Sinclair et al., 2014; Thomas & Abram, 2016). While there is reasonable broad-scale concurrence across these estimates, the uncertainties are large, there is considerable interannual variability, and reconstructions require further validation (Hobbs et al., 2016a,b). New reconstructions (Thomas et al., 2019) from Antarctic land ice cores show that SIE in the Ross Sea had increased between 1900 and 1990, while the Bellingshausen Sea had experienced a decline in SIE; this dipole pattern is consistent with satellite-based observations from 1979 to 2019 (Parkinson, 2019), but the recent rate of change then has been larger. Records of Antarctic SIE for the late 19th and early 20th centuries (Edinburgh and Day, 2016), show SIE comparable with the satellite era, although with marked spatial heterogeneity (e.g., Thomas et al., 2019).

Early Nimbus satellite visible and infrared imagery from the 1960s (Meier et al., 2013; Gallaher et al., 2014) indicate higher overall SIE compared to 1979–2013 (Hobbs et al., 2016a,b), but with large uncertainties and poorly quantified biases (NA SEM, 2017). The continuous satellite passive-microwave record shows that there was a modest increase in overall Antarctic SIA of 2.5% ± 0.2% per decade (1 standard error over 1979–2015 (Comiso et al., 2017). For overall ice coverage and for this period, positive long-term trends were most pronounced during austral autumn advance (Maksym, 2019), being moderate in summer and winter, and lowest in spring (Comiso et al., 2017; Hobbs et al., 2016a,b; Holland, 2014; Turner et al., 2015). Since 2014, overall Antarctic SIE (and SIA) has exhibited major fluctuations from record-high to record-low satellite era extents (Comiso et al., 2017; Massonnet et al., 2015; Parkinson, 2019; Reid, and Massom, 2015; Reid et al., 2015). After setting record-high extents each September from 2012 through 2014, Antarctic SIE (and SIA) dipped rapidly in mid-2016 and remained predominantly below average through 2019 (Reid et al., 2020). For the most recent decade of observations (2010–2019), the decadal means of three SIA products (Figure 2.20b) were 2.17 million km^2 for February and 15.75 million km^2 for September, respectively. The corresponding levels for the means for the first decade of recordings (1979–1988) were 2.04 million km^2 for February and 15.39 million km^2 for September indicating little overall change. Initial SIA data for 2020 (OSISAF) show SIA for September above, and for February slightly below the recent decadal means (Fig. 2.20b). The 2020 September level (OSISAF) remains below the levels observed over 2012–2014.

In summary, Antarctic sea ice has experienced both increases and decreases in SIA over 1979–2019, and substantively lower levels since 2016, with only minor differences between decadal means of SIA for the first (for February 2.04 million km^2, for September 15.39 million km^2) and last decades (for February 2.17 million km^2, for September 15.75 million km^2) of satellite observations (*high confidence*). There remains *low*

ACCEPTED VERSION SUBJECT TO FINAL EDITS

confidence in all aspects of Antarctic sea ice prior to the satellite era owing to a paucity of records that are highly regional in nature and often seemingly contradictory.

2.3.2.2 Terrestrial snow cover

AR5 concluded that snow cover extent (SCE) had decreased in the NH, especially in spring *(very high confidence)*. For 1967–2012, the largest change was in June and March-April SCE *very likely* declined. No trends were identified for the SH due to limited records and large variability. SROCC concluded with *high confidence* that Arctic June SCE declined between 1967 and 2018 and in nearly all mountain regions, snow cover declined in recent decades.

Analysis of the combined in situ observations (Brown, 2002) and the multi-observation product (Mudryk et al. 2020) indicates that since 1922, April SCE in the NH has declined by 0.29 million km^2 per decade, with significant interannual variability (Figure 2.22) and regional differences (Section 9.5.3.1). The limited pre-satellite era data does not allow for a similar assessment for the entire spring-summer period. Assessment of SCE trends in the NH since 1978 indicates that for the October to February period there is substantial uncertainty in trends with the sign dependent on the observational product. Analysis using the NOAA Climate Data Record shows an increase in October to February SCE (Hernández-Henríquez et al., 2015; Kunkel et al., 2016) while analyses based on satellite borne optical sensors (Hori et al., 2017) or multi-observation products (Mudryk et al., 2020) show a negative trend for all seasons (section 9.5.3.1, Figure 9.23). The greatest declines in SCE have occurred during boreal spring and summer, although the estimated magnitude is dataset dependent (Rupp et al., 2013; Estilow et al., 2015; Bokhorst et al., 2016; Thackeray et al., 2016; Connolly et al., 2019).

[START FIGURE 2.22 HERE]

Figure 2.22: April snow cover extent (SCE) for the Northern Hemisphere (1922–2018). Shading shows *very likely* range. The trend over the entire 1922–2018 period (black line) is –0.29 (± 0.07) million km^2 per decade. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.22 HERE]

There has been a commensurate decrease in the snow-cover duration and persistence, particularly in higher latitudes due to earlier spring melt and, in some cases, later autumn onset of snow cover (Chen Xiaona et al., 2015; Derksen et al., 2015; Hammond et al., 2018; Hori et al., 2017). Arctic snow-cover duration has decreased by 2–4 days per decade since the 1970s (Brown et al., 2017). Significant decreases in snow-cover duration have been documented over western Eurasia since 1978 (Hori et al., 2017).

For the NH, maximum snow depth has generally decreased since the 1960s, with more robust trends for North America and greater uncertainty for Eurasia (Kunkel et al., 2016). Several satellite-based passive microwave and other products indicate general declines in pre-melt snow water equivalent since 1981 although there is regional and inter-dataset variability (Brown et al., 2017; Jeong et al., 2017; Marty et al., 2017; Mortimer et al., 2020; Mudryk et al., 2020; Pulliainen et al., 2020, Section 9.5.3).

In summary, substantial reductions in spring snow cover extent have occurred in the NH since 1978 (*very high confidence*) with *limited evidence* that this decline extends back to the early 20th century. Since 1981 there has been a general decline in NH spring snow water equivalent (*high confidence*).

2.3.2.3 Glacier mass

AR5 concluded with *high confidence* that, during the Holocene, glaciers were at times smaller than at the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

end of the 20th century. AR5 stated further with *very high confidence* that most glaciers had been shrinking since the mid-1800s, and the mass loss from all glaciers worldwide *very likely* increased from 1970 to 2009. SROCC reported a globally coherent picture of continued glacier recession in recent decades (*very high confidence*) based on in situ and satellite observations of changes in glacier area, length and mass, although there were considerable inter-annual and regional variations. Between 2006 and 2015 the global glacier mass change assessed by SROCC was –278 ± 113 Gt yr^{-1}.

Two recent global reviews on glaciers over the Holocene (Solomina et al., 2015) and the past 2 kyr (Solomina et al., 2016) summarize the chronologies of respectively 189 and 275 glaciers. The former shows that glaciers retreated during the LDT and retracted to their minimum extent between 8 ka and 6 ka. Except for some glaciers in the SH and tropics, glaciers expanded thereafter, reaching their maximum extent beyond their present-day margins during the mid-1400s to late-1800s CE. With few exceptions, glacier margins worldwide have retreated since the 19th century, with the rate of retreat and its global character since the late 20th century being unusual in the context of the Holocene (Solomina et al., 2016, Figure 2.23a). However, the areal extents of modern glaciers in most places in the NH are still larger than those of the early and/or middle Holocene (Solomina et al., 2015). When considering Holocene and present glaciers extents, it is important to account for the relatively long adjustment time of glaciers (often referred to as response time; Section 9.5.1.3); the majority of modern glaciers are currently out of equilibrium with current climate, even without further global warming (Christian et al., 2018; Marzeion et al., 2018; Mernild et al., 2013; Zekollari et al., 2020). The size of glaciers during other periods warmer than the Early to Mid-Holocene, such as the MPWP and LIG, is largely unknown because the deposits marking previous extents were in almost all cases over-ridden by later glaciations. For Arctic glaciers, different regional studies consistently indicate that in many places glaciers are now smaller than they have been in millennia (Harning et al., 2016, 2018; Lowell et al., 2013; Miller et al., 2013, 2017; Pendleton et al., 2019; Schweinsberg et al., 2017, 2018)

New glacier outline (RGI Consortium, 2017) and glacier mass compilations (Ciracì et al., 2020; Hugonnet et al., 2021; Zemp et al., 2019; 2020) improve, refine and update the quantification of glacier areal and mass changes based on observations from in situ and remote sensing data. Observations between the 1960s and 2019 indicate that mass loss has increased over recent decades (Figure 2.23b). The overall global glacier mass loss rate has increased from 240 ± 9 Gt yr^{-1} over 2000–2009 to 290 ± 10 Gt yr^{-1} over 2010–2019 (Hugonnet et al., 2021), confirming that the last decade exhibits the most negative glacier mass balance since the beginning of the observational record. Observations are in general consistent with trends revealed by global glacier mass change modelling for almost the entire 20th century (1901–1990) implying an estimated mass loss (without uncharted glaciers (Parkes and Marzeion, 2018) and excluding peripheral glaciers of Greenland and Antarctica) of *very likely* 210 ± 90 Gt yr^{-1} and *very likely* 170 ± 80 Gt yr^{-1} for the period 1971–2019 (Marzeion et al., 2015; Section 9.5.1 and Table 9.5).

[START FIGURE 2.23 HERE]

Figure 2.23: Glacier advance and annual mass change. (a) Number of a finite selection of surveyed glaciers that advanced during the past 2000 years. (b) Annual and decadal global glacier mass change (Gt yr^{-1}) from 1961 until 2018. In addition, mass change mean estimates are shown. Ranges show the 90% confidence interval. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.23 HERE]

In summary, there is *very high confidence* that, with few exceptions, glaciers worldwide have retreated since the second half of the 19th century, and continue to retreat. The current global character of glacier mass loss is highly unusual (almost all glaciers simultaneously receding) in the context of at least the last 2 kyr (*medium confidence*). Glacier mass loss rates have increased since the 1970s (*high confidence*). Although many surveyed glaciers are currently more extensive than during the MH (*high confidence*), they generally are in disequilibrium with respect to current climate conditions and hence are committed to further ice loss.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.3.2.4 Ice sheet mass and extent

During glacial periods, ice sheets were more extensive and the state of knowledge on their paleo-reconstruction can be found in recent publications (e.g. Batchelor et al., 2019; Stokes et al., 2015). This section focuses only on the large-scale aspects of those ice sheets, Greenland and Antarctic, that still exist today.

2.3.2.4.1 Greenland Ice Sheet

AR5 concluded the volume of the Greenland Ice Sheet (GrIS) was reduced compared to present during periods of the past few million years that were globally warmer than present (*high confidence*). It reported that the GrIS had lost ice during the prior two decades (*very high confidence*), that the ice loss had occurred in several sectors, and that high rates of mass loss had both expanded to higher elevations (*high confidence)* and *very likely* accelerated since 1992. SROCC concluded that it was *extremely likely* that ice loss increased through the early 21st century. SROCC also found that summer melting rate had increased since the 1990s to a rate unprecedented over the last 350 years *(very high confidence*), being two to five times greater than the pre-industrial rates (*medium confidence*).

Details of the history of GrIS fluctuations during warm interglacials continue to be elucidated. Oscillations over the past 7.5 Myr, including the Pliocene and through the glacial - interglacial cycles of the Pleistocene are not well-constrained, but most studies indicate that Greenland was at least partially glaciated over this time with extended periods when it was predominantly deglaciated (Schaefer et al., 2016, Bierman et al., 2016). Geological evidence and modelling studies suggest periods of glacial intensification during the Pliocene at 4.9 Myr, 4.0 Myr, 3.6 Myr and 3.3 Myr (De Schepper et al., 2014; Bierman et al., 2016; Bachem et al., 2017). Retreat of the GrIS occurred during the MPWP and GrIS extent was reduced compared to today with some studies suggesting that the ice sheet was limited to the highest elevations (Blake-Mizen et al., 2019; De Schepper et al., 2014; Haywood et al., 2016; Koenig et al., 2015). There is apparent glacial intensification following the MPWP, 2.75–2.72 Myr (Nielsen and Kuijpers, 2013; De Schepper et al., 2014; Blake-Mizen et al., 2019; Knutz et al., 2019). Several studies agree that during the LIG the total GrIS extent was *likely* less than present day (Section 9.4.1, Figure 9.17) with the total mass loss ranging from 0.3–6.2 m sea level equivalent (SLE), although timing and magnitude of this mass loss are not well constrained (Clark et al., 2020; Goelzer et al., 2016; Helsen et al., 2013; Sinclair et al., 2016; Stone et al., 2013; Vasskog et al., 2015; Yau et al., 2016). During the LGM, the GrIS reached a peak ice volume greater than present (2–5 m SLE), as revealed by limited number of available geological records (Lecavalier et al., 2014; Simpson et al., 2009; Batchelor et al. 2019).

Recent studies of marine and lake sediments, glacier ice, and geomorphic features show that the GrIS retreated rapidly during the early Holocene but halted periodically, with a complex ice-margin chronology (Briner et al., 2016; Carlson et al., 2014; Larsen et al., 2014, 2015; Young et al., 2020; Young & Briner, 2015). It is probable that its total volume during 8–3 ka was smaller than today (Briner et al., 2016; Larsen et al., 2015; Young & Briner, 2015), but uncertainties exist regarding precisely when the minimum MH extent and volume was reached, due to uncertainties in reconstructions. The GrIS then re-advanced reaching its maximum extent in most places during 1450–1850 CE, although the timing and extent of this maximum differed by sector (Briner et al., 2016; Larsen et al., 2015).

Greenland-wide estimates of mass change based on direct observations were limited prior to 1992 at the time of AR5 (Kjeldsen et al., 2015). Combined records based on airborne observations, model-based estimates and geodetic approaches indicate an average mass loss of 75 ± 29.4 Gt yr^{-1} for 1900–1983 (Kjeldsen et al., 2015). Integration of proxies and modelling indicates that the last time the rate of mass loss of GrIS was plausibly similar to 20th century rates was during the early Holocene (Briner et al., 2020; Buizert et al., 2018).

Since AR5, a combination of remote sensing, in situ observations and modelling has provided new insights regarding surface processes and their contribution to recent GrIS mass changes (AMAP, 2017; Bamber et al., 2018; IMBIE Consortium, 2020; Khan et al., 2020; Mouginot et al., 2019; van den Broeke et al., 2017).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Estimates of total ice loss during the post-1850 period (Kjeldsen et al., 2015) and recent observations show that the rate of loss has increased since the beginning of the 21st century (IMBIE Consortium, 2020; Sasgen et al., 2020; Velicogna et al., 2020) (Figure 2.24, Section 9.4.1.1 Figure 9.17).

The GrIS lost 4890 [4140–5640] Gt (SLE 13.5 [11.4–15.6] mm) of ice between 1992 and 2020 (IMBIE Consortium, 2020) (Figure 2.24, Section 9.4.1). The ice sheet was close to mass balance in the 1990s, but increases in mass loss have occurred since (Bamber et al., 2018; WCRP Global Sea Level Budget Group, 2018; Mouginot et al., 2019; IMBIE Consortium, 2020). The rate of ice sheet (including peripheral glaciers) mass loss rose from 120 [70 to 170] Gt yr^{-1} (SLE 0.33 [0.18 to 0.47] mm yr^{-1}) in 1901–1990 to 330 [290 to 370] Gt yr^{-1} (SLE 0.91 [0.79 to 1.02] mm yr^{-1}) for 2006–2018 (Section 9.4.1, Table 9.5).

[START FIGURE 2.24 HERE]

Figure 2.24: Cumulative Antarctic Ice Sheet (AIS) and Greenland Ice Sheet (GrIS) mass changes. Values shown are in gigatons and come from satellite-based measurements (IMBIE Consortium, 2018, 2020) for the period 1992–2018 for GrIS and 1992–2017 for AIS. The estimated uncertainties, *very likely* range, for the respective cumulative changes are shaded. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.24 HERE]

In summary, the GrIS was smaller than present during the MPWP (*medium confidence*), LIG (*high confidence*) and the MH (*high confidence*). GrIS mass loss began following a peak volume attained during the 1450–1850 period and the rate of loss has increased substantially since the turn of the 21st century (*high confidence*).

2.3.2.4.2 Antarctic Ice Sheet

AR5 reported that there was *high confidence* that the AIS was losing mass. The average ice mass loss from Antarctica was 97 [58 to 135] Gt yr^{-1} (GMSL equivalent of 0.27 [0.16 to 0.37] mm yr^{-1}) over 1993–2010, and 147 [74 to 221] Gt yr^{-1} (0.41 [0.20 to 0.61] mm yr^{-1}) over 2005–2010. These assessments included the Antarctic peripheral glaciers. AR5 reported with *high confidence* that the volume of the West Antarctic Ice Sheet (WAIS) was reduced during warm periods of the past few million years. SROCC concluded that over 2006–2015, the AIS lost mass at an average rate of 155 ± 19 Gt yr^{-1} (*very high confidence*). SROCC stated also that it is *virtually certain* that the Antarctic Peninsula and WAIS combined have cumulatively lost mass since widespread measurements began in 1992, and that the rate of loss has increased since around 2006.

Process understanding and, to some extent, paleoclimate records show that changes in parts of the AIS can occur over multi-century time scales (<2kyr) (e.g. Dowdeswell et al., 2020; Sections 9.4.2.3 and 9.6.2). Based on physical understanding, paleo evidence and numerical simulations, it is *very likely* that the AIS has been smaller than today during at least some past warm climates (such as MCO and LIG), in particular the WAIS (de Boer et al., 2015; Deconto & Pollard, 2016; Golledge et al., 2014; Levy et al., 2016) (Figure 9.18). Results from sediment studies suggest a smaller AIS during the MPWP compared with current levels, with main differences in the WAIS (SROCC, Bertram et al., 2018; Shakun et al., 2018, Section 9.6.2). Marine sediments indicate that during the Pleistocene repeated ungrounding and loss of large marine-based parts of the AIS occurred during interglacial periods, with at least seven transitions between floating and grounded ice in the Ross Sea during the last 780 kyr (McKay et al., 2012) and at least three reductions in ice volume in the Wilkes Basin during the last 500 kyr (Wilson et al., 2018). Proxies, modelling and process understanding (Rohling et al., 2019; Clark et al., 2020) indicate that the AIS was smaller during the LIG than present.

Geological evidence has been used to reconstruct Holocene glacial fluctuations of the ice sheet margin and lowerings of its surface, which occurred at different times in different places, as recently reviewed by Noble et al. (2020). In West Antarctica, marine sediments below the ice sheet (Kingslake et al., 2018) corroborate a

ACCEPTED VERSION SUBJECT TO FINAL EDITS

previous glacial isostatic adjustment modelling study (Bradley et al., 2015), which suggests that ice had retreated behind the present grounding line prior to about 10 ka, and then readvanced. Geophysical imaging indicates a readvance in this area around 6 ± 2 ka (Wearing and Kingslake, 2019). Other studies from the region conclude that ice sheet retreat and thinning was fastest from 9 to 8 ka (Johnson et al., 2014; McKay et al., 2016; Spector et al., 2017), or millennia later, during the MH (Hein et al., 2016; Johnson et al., 2019), with indications of a subsequent readvance (Venturelli et al., 2020). In East Antarctica, rapid ice sheet thinning occurred between around 9 and 5 ka (Jones et al., 2015), consistent with previous work indicating that the ice sheet in many regions was at or close to its current position by 5 ka (Bentley et al., 2014). Overall, during the MH, the AIS was retreating, but remained more extensive than present, while some parts of the ice sheet might have been smaller than now (*low confidence*).

Improved estimates of surface mass balance (SMB) in Antarctica from 67 ice core records do not show any substantial changes in accumulation rates over most of Antarctica since 1200 CE (Frezzotti et al., 2013). The SMB growth rate in Antarctica is estimated to be 7.0 ± 0.1 Gt per decade between 1800 and 2010 and 14.0 ± 1.8 Gt per decade since 1900 (Thomas et al., 2017). For the period 1979–2000, an insignificant Antarctic-wide negative SMB trend has been estimated (Medley and Thomas, 2019). The Antarctic Ice Sheet lost 2670 [1800 to 3540] Gt (SLE 7.4 [5.0 to 9.8] mm) of ice between 1992 and 2020. The rate of ice sheet (including peripheral glaciers) mass loss rose from 0 [–36 to 40] Gt yr^{-1} (SLE 0.0 [–0.10 to 0.11] mm yr^{-1}) in 1901–1990 to 192 [145 to 239] Gt yr^{-1} (SLE 0.54 [0.47 to 0.61] mm yr^{-1}) for 2006–2018 (Figure 2.24, Section 9.4.2, Table 9.5). Within quantified uncertainties, this estimate agrees with other recent estimates (Rignot et al., 2019; Smith et al., 2020; Velicogna et al., 2020). There is therefore *very high confidence* that the AIS has been losing mass over 1992–2020 (Figure 2.24, Section 9.4.2.1). Major contributions to recent AIS changes arise from West Antarctica and Wilkes Land in East Antarctica (Rignot et al., 2019). For the East Antarctic most studies suggest that the mass balance is not significantly different from zero (Bamber et al., 2018; IMBIE Consortium, 2018; Mohajerani et al., 2018; Rignot et al., 2019).

In summary, the AIS has lost mass between 1992 and 2020 (*very high confidence*), and there is *medium confidence* that this mass loss has increased. During the MPWP and LIG, the ice sheet was smaller than present (*medium confidence*). There is *low confidence* as to whether the total mass of the ice sheet was larger or smaller around 6 ka compared to now.

2.3.2.5 Terrestrial permafrost

AR5 concluded that in most regions and at most monitoring sites permafrost temperatures since the 1980s had increased (*high confidence*). Negligible change was observed at a few sites, mainly where permafrost temperatures were close to 0°C, with slight cooling at a limited number of sites. AR5 also noted positive trends in active layer thickness (ALT; the seasonally thawed layer above the permafrost) since the 1990s for many high latitude sites (*medium confidence*). SROCC concluded permafrost temperatures have increased to record high levels since the 1980s (*very high confidence*) with a recent increase by 0.29°C ± 0.12°C from 2007 to 2016 averaged across polar and high mountain regions globally.

Permafrost occurrence during the Pliocene has been inferred from pollen in lake sediments in NE Arctic Russia and permafrost-vegetation relationships which indicate that permafrost was absent during the MPWP in this region (Brigham-Grette et al., 2013; Herzschuh et al., 2016). Analysis of speleothem records in Siberian caves, indicates that permafrost was absent in the current continuous permafrost zone at 60°N at the start of the 1.5 Ma record, with aggradation occurring around 0.4 Ma (Vaks et al., 2020). There are indications of extensive permafrost thaw during subsequent interglacials especially further south in the current permafrost zone (Vaks et al., 2013). Reconstruction of permafrost distribution during the LGM indicates that permafrost was more extensive in exposed areas (Vandenberghe et al., 2014). In non-glaciated areas of the North American Arctic there is permafrost that survived the LIG (French and Millar, 2014). Trends and timing of permafrost aggradation and thaw over the last 6 kyr in peatlands of the NH were recently summarized (Hiemstra, 2018; Treat and Jones, 2018a). Three multi-century periods (ending 1000 Before the Common Era (BCE), 500 CE and 1850 CE) of permafrost aggradation, associated with neoglaciation periods are inferred resulting in more extensive permafrost in peatlands of the present-day discontinuous permafrost zone, which reached a peak approximately 250 years ago, with thawing occurring

ACCEPTED VERSION SUBJECT TO FINAL EDITS

concurrently with post 1850 warming (Treat and Jones, 2018b). Although permafrost persists in peatlands at the southern extent of the permafrost zone where it was absent prior to 3 ka, there has been thawing since the 1960s (Holloway & Lewkowicz, 2020; James et al., 2013; Jones et al., 2016).

Records of permafrost temperature measured in several boreholes located throughout the northern polar regions indicate general warming of permafrost over the last 3–4 decades (Figure 2.25), with marked regional variations (Romanovsky et al., 2017a,b; 2020; Biskaborn et al., 2019). Recent (2018–2019) permafrost temperatures in the upper 20–30 m layer (at depths where seasonal variation is minimal) were the highest ever directly observed at most sites (Romanovsky et al., 2020), with temperatures in colder permafrost of northern North America being more than 1°C higher than they were in 1978. Increases in temperature of colder Arctic permafrost are larger (average 0.4°C–0.6°C per decade) than for warmer (temperature >–2°C) permafrost (average 0.17°C per decade) of sub-Arctic regions (Figures 2.25, 9.22).

[START FIGURE 2.25 HERE]

Figure 2.25: Changes in permafrost temperature. Average departures of permafrost temperature (measured in the upper 20–30 m) from a baseline established during International Polar Year (2007–2009) for Arctic regions. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.25 HERE]

Increases in permafrost temperature over the last 10–30 years of up to 0.3°C per decade have been documented at depths of about 20 m in high elevation regions in the NH (European Alps, the Tibetan Plateau and some other high elevation areas in Asia; Biskaborn et al., 2019; Cao et al., 2018; Liu G. et al., 2017; Noetzli et al., 2020; Zhao et al., 2020). In Antarctica, where records are limited and short (most < 10 years) trends are less evident (Noetzli et al. 2019).

Assessment of trends in ALT is complicated by considerable ALT interannual variability. For example, in north-western North America during the extreme warm year of 1998, ALT was greater than in prior years. Although ALT decreased over the following few years, it has generally increased again since the late 2000s (Duchesne, et al. 2015; Romanovsky et al., 2017b; 2020). However, at some sites there has been little change in ALT due to ground subsidence that accompanies thaw of ice-rich permafrost (Streletskiy et al., 2017; O'Neill et al., 2019). In the European and Russian Arctic there has been a broad-scale increase in ALT during the 21st century (Streletskiy et al., 2015; Romanovsky et al., 2020). In high elevation areas in Europe and Asia, increases in ALT have occurred since the mid-1990s (Cao et al., 2018; Liu, Y. et al., 2017; Noetzli et al., 2019; 2020; Zhao et al., 2020). Limited and shorter records for Antarctica show marked interannual variability and no apparent trend with ALT being relatively stable or decreasing at some sites since 2006 (Hrbáček et al., 2018).

Observations of ground subsidence and other landscape change (e.g. thermokarst, slope instability) since the middle of the 20th century in the Arctic associated with ground ice melting have been documented in several studies and provide additional indications of thawing permafrost (Borge et al., 2017; Derksen et al., 2019; Farquharson et al., 2019; Kokelj et al., 2017; Lewkowicz & Way, 2019; Liljedahl et al., 2016; Nitze et al., 2017; O'Neill et al., 2019; Séjourné et al., 2015; Streletskiy et al., 2017; Section 9.5.2.1). In mountain areas, destabilization and acceleration of rock glacier complexes that may be associated with warming permafrost have also been observed (Eriksen et al., 2018; Marcer et al., 2019).

In summary, increases in permafrost temperatures in the upper 30 m have been observed since the start of observational programs over the past three to four decades throughout the permafrost regions (*high confidence*). *Limited evidence* suggests that permafrost was less extensive during the MPWP (*low confidence*). Permafrost that formed after 3ka still persists in areas of the NH, but there are indications of thaw after the mid-1800s (*medium confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.3.3 Ocean

This section focuses on large-scale changes in a subset of physical components of the ocean (Cross-Chapter Box 2.2). Chapter 7 assesses the role of the ocean in Earth system heating and evaluates the Earth's energy budget. Chapter 9 undertakes a holistic assessment of changes in the ocean integrating observations, modelling and theoretical understanding. Chapter 11 assesses extremes such as marine heat waves and storm surges. SSTs are assessed in Section 2.3.1.1 as they constitute a critical component of GMST estimation.

2.3.3.1 Ocean temperature, heat content and thermal expansion

AR5 assessed that since 1971, global ocean warming was *virtually certain* for the upper 700 m and *likely* for the 700–2000 m layer. SROCC reported linear warming trends for the 0–700 m and 700–2000 m layers of the ocean of 4.35 ± 0.8 and 2.25 ± 0.64 ZJ yr^{-1} over 1970-2017; 6.28 ± 0.48 and 3.86 ± 2.09 ZJ yr^{-1} over 1993–2017; and 5.31 ± 0.48 and 4.02 ± 0.97 ZJ yr^{-1} over 2005–2017. Both AR5 and SROCC assessed that the ocean below 2000 m had *likely* warmed since 1992. SROCC reported global mean thermosteric sea level (ThSL) rise, associated with thermal expansion of the ocean, with a trend of 0.89 ± 0.05 mm yr^{-1} for 1970–2015; 1.36 ± 0.40 mm yr^{-1} for 1993–2015; and 1.40 ± 0.40 mm yr^{-1} for 2006–2015, and also reported that the rate of ocean warming over 1993-2017 had *likely* more than doubled since 1969–1992.

New ocean heat content (OHC) reconstructions derived from paleo proxies (Baggenstos et al., 2019; Bereiter et al., 2018; Gebbie, 2021; Shackleton et al., 2019) indicate that the global ocean warmed by 2.57°C ± 0.24°C, at an average rate of ~0.3°C ka^{-1} (equivalent to an OHC change rate of 1.3 ZJ yr^{-1}) from the LGM (~20 ka) to the early Holocene (~10 ka) (Figure 9.9, Section 9.2.2.1). Over the LDT, ocean warming occurred in two stages, offset by some heat loss during the Antarctic Cold Reversal (14.58–12.75 ka). Only during a short period of rapid warming at the end of the Younger Dryas (12.75–11.55 ka) were rates comparable to those observed since the 1970s (Bereiter et al., 2018; Shackleton et al., 2019). Ice cores imply a small decrease in the global mean ocean temperature during the early Holocene (<0.4°C) (Baggenstos et al., 2019; Bereiter et al., 2018). Sediment cores from the equatorial Pacific and Atlantic Ocean (0–1000 m) indicate a stronger regional cooling (compared to mean ocean temperature) of 1.0°C ± 0.7°C to 1.8°C ± 0.4°C from the early/mid-Holocene to ca.1750 CE (Kalansky et al., 2015; Morley et al., 2014; Rosenthal et al., 2017; 2013). Sediment cores from the western equatorial Pacific suggest 0.8°C ± 0.1°C higher temperatures in the upper 700 m of the ocean during 950–1100 CE compared to 1400–1750 CE. These changes are consistent with a global estimate derived from combined surface and subsurface ocean temperature proxy records (McGregor et al., 2015; PAGES 2k Consortium, 2013). A combined study of model and observational data further confirmed these results, treating temperature as a passive tracer (Gebbie & Huybers, 2019) and addressing the role of circulation dynamics (Scheen and Stocker, 2020). Collectively, the proxy records indicate a global OHC decrease of ~400 ± 70 ZJ (~170 ± 100 ZJ in the Pacific) in the upper 700 m between 950–1100 CE and 1400–1750 CE, and also suggest that the deep Pacific is still adjusting to this cooling (Rosenthal et al., 2013), partially offsetting the global increase since 1750 CE (Gebbie & Huybers, 2019; Gebbie, 2021).

For the instrumental era, since AR5 and SROCC, new and updated OHC (and ThSL) observation-based analyses (Johnson et al., 2020; von Schuckmann et al., 2020) enhance an existing large ensemble of direct and indirect OHC estimates (Figure 2.26), although some rely to varying degrees upon information from ocean-climate models. Direct estimates benefit from improved: bias adjustments (e.g. Bagnell & DeVries, 2020; Cheng et al., 2018; Gouretski & Cheng, 2020; Leahy et al., 2018; Palmer et al., 2018; Ribeiro et al., 2018; Wang et al., 2018); interpolation methods (Kuusela & Stein, 2018; Su et al., 2020); and characterization of sources of uncertainty (e.g.(Allison et al., 2019; Garry et al., 2019; Good, 2017; Meyssignac et al., 2019; Palmer et al., 2021; Wunsch, 2018), including those originating from forced and intrinsic ocean variability (Penduff et al. 2018). After 2006 direct OHC estimates for the upper 2000 m layer benefit from the near-global ARGO array with its superior coverage over 60°S–60°N (Roemmich et al., 2019). Indirect estimates include OHC and ThSL series inferred from satellite altimetry and gravimetry since 2003 (Meyssignac et al., 2019), the passive uptake of OHC (ThSL) at centennial timescales inferred from observed SST anomalies, and time-invariant circulation processes from an ocean state estimation (e.g. Zanna

ACCEPTED VERSION SUBJECT TO FINAL EDITS

et al., 2019). Resplandy et al. (2019) estimate the rate of global OHC uptake over 1991–2016 from changes in atmospheric composition and physical relationships based on CMIP5 model simulations. The uncertainties are broader than from direct estimates but the estimate is qualitatively consistent.

Collectively, the new and updated analyses strengthen AR5 and SROCC findings of a sustained increase in global OHC (Figure 2.26, Table 2.7) and associated ThSL rise. Larger warming rates are observed in the upper 700 m compared to deeper layers, with more areas exhibiting significant warming than significant cooling (Johnson & Lyman, 2020). There is an improved consistency among available estimates of OHC rates in the upper 2000 m since 2006. Cheng et al. (2020), von Schuckmann et al. (2020) and Johnson et al. (2020) have further confirmed that the central estimates of rates of OHC change in the upper 2000 m depths have increased after 1993 and particularly since 2010 (Section 3.5.1.3, Figures 2.26, 3.26), although uncertainties are large (Table 2.7). Ocean reanalyses support findings of continued upper ocean warming (Balmaseda et al., 2013; Meyssignac et al., 2019; von Schuckmann et al., 2018), albeit with higher spread than solely observational estimates, particularly in the poorly sampled deep ocean below 2000 m (Palmer et al., 2018; Storto et al., 2017).

In summary, current multidecadal to centennial rates of OHC gain are greater than at any point since the last deglaciation (*medium confidence*). At multi-centennial timescales, changes in OHC based upon proxy indicators demonstrate a tight link with surface temperature changes during the last deglaciation (*high confidence*), as well as during the Holocene and CE (*low confidence*). It is *likely* the global ocean has warmed since 1871, consistent with the observed increase in sea surface temperature. It is *virtually certain* that OHC increased between 1971 and 2018 in the upper 700 m and *very likely* in the 700–2000 m layer, with *high confidence* since 2006. It is *likely* the OHC below 2000 m has increased since 1992. Confidence in the assessment of multidecadal OHC increase is further strengthened by consistent closure of both global sea level and energy budgets (Section 7.2.2.2, Box 7.2, Cross-Chapter Box 9.1).

[START FIGURE 2.26 HERE]

Figure 2.26: Changes in Ocean heat content (OHC). Changes are shown over (a) full depth of the ocean from 1871 to 2019 from a selection of indirect and direct measurement methods. The series from Table 2.7 is shown in solid black in both (a) and (b) (see Table 2.7 caption for details). (b) as (a) but for 0–2000 m depths only and reflecting the broad range of available estimates over this period all of which are broadly similar. For further details see chapter data table (Table 2.SM.1).

[END FIGURE 2.26 HERE]

[START TABLE 2.7 HERE]

Table 2.7: Rates of global ocean heat content (OHC) and global mean thermosteric sea level ThSL change for four depth integrations over different periods. For the period up to 1971, the assessment for all depth layers is based on Zanna et al (2019). From 1971 onwards, consistent with AR5, Domingues et al. (2008, updated) is the central estimate for 0–700 m along with uncertainty from a 5-member ensemble (Cheng et al., 2017; Domingues et al., 2008; updated; Good et al., 2013; Ishii et al., 2017; Levitus et al., 2012), following the approach of Palmer et al (2021). Similarly, Ishii et al. (2017) is the central estimate for 700–2000 m with uncertainty based on a 3-member ensemble (Cheng et al., 2017; Ishii et al., 2017; Levitus et al., 2012). For depths below 2000 m, both central estimate and uncertainty are from Purkey and Johnson (2010, updated). In cases when OHC estimates do not have a ThSL counterpart (e.g. Cheng et al., 2017; Good et al., 2013), OHC was converted into ThSL using the average linear regression coefficients for 0–700 m and 700–2000 m from all available ensemble members. For consistency with the energy and sea-level budgets presented in Chapters 7 and 9, reported rates are based on the difference between the first and last annual mean value in each period (Palmer et al., 2021, Box 7.2, Cross-Chapter Box 9.1). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END TABLE 2.7 HERE]

2.3.3.2 Ocean salinity

AR5 concluded that subtropical regions of high salinity (where evaporation dominates over precipitation) had become more saline, while regions of low salinity (mostly in the tropics and high latitudes) had *very likely* become fresher since the 1950s, both at the near-surface, and in the ocean interior along ventilation pathways. From 1950 to 2008, the mean surface contrast between high- and low-salinity regions increased by 0.13 [0.08 to 0.17] (PSS-78, Unesco, 1981). Across basins, the Atlantic Ocean had become saltier and the Pacific and Southern Oceans had freshened (*very likely*).

Prior to the instrumental record, reconstructions of near-surface salinity change are accomplished by combining isotopic and elemental proxy data from microfossil plankton shells and skeletons preserved in deep-sea sediments. These data highlight changes in the salinity contrast between the Pacific and Atlantic oceans during past ice ages (Broecker, 1989; Keigwin and Cook, 2007; Costa et al., 2018) and for repeated

ACCEPTED VERSION SUBJECT TO FINAL EDITS

episodes of increased subtropical salinity (Schmidt et al., 2004, 2006) and subpolar freshening (Cortijo et al., 1997; Thornalley et al., 2011) in the North Atlantic ocean. These episodes were associated with disruptions to the large-scale deep ocean circulation (Buizert et al., 2015; Henry et al., 2016; Lynch-Stieglitz, 2017). Further quantification of paleo salinity changes is complicated by incomplete understanding on how proxy-salinity relationships and the relative influence of atmospheric and ocean processes vary across regions and paleo periods (Conroy et al., 2017; Holloway et al., 2016; LeGrande & Schmidt, 2011; Rohling, 2007).

Since AR5, new and extended multidecadal analyses have strengthened the observational support for increased contrast between high and low near-surface salinity regions and inter-basin contrast since the mid-20th century (Section 9.2.2.2; Aretxabaleta et al., 2017; Cheng et al., 2020; Durack & Wijffels, 2010; Good et al., 2013; Skliris et al., 2014). These analyses employ different statistical algorithms for interpolation, and only Cheng et al., (2020) use CMIP5 model simulations to constrain observation-based signals in data-sparse regions.

The 1950–2019 trends reveal near-surface freshening of the northern and western Warm (and fresh) Pool of the Pacific and increased salinity maxima in the subtropical Atlantic, strengthening the inter-basin contrast (Figure 2.27a). There are indications that the subpolar freshening and subtropical salinification of the Atlantic ocean may extend back to at least 1896 (Friedman et al., 2017). Over recent decades, new observations from Argo floats and ocean reanalyses provide general support that changes in the global patterns of near-surface salinity contrast are broadly associated with an intensification of the hydrological cycle (Sections 2.3.1.3.5; 8.3.1.1). However, this assessment is complicated by changing observational techniques (Section 1.5.1), temporally and spatially inhomogeneous sampling and uncertainties in interpolation algorithms and the substantial influence of modes of natural variabiltity and ocean circulation processes over interannual timescales (Aretxabaleta et al., 2017; Durack, 2015; Grist et al., 2016; Liu et al., 2020; Skliris et al., 2014; Vinogradova & Ponte, 2017). Following AR5, based on the updated analysis from Durack and Wijffels (2010) which infills in situ gaps to recover large-scale patterns the mean salinity contrast between high- and low- near-surface salinity regions increased by 0.14 [0.07 to 0.20] from 1950 to 2019.

Changes in the global patterns of near-surface salinity contrast are transferred to the ocean interior via ventilation pathways (Figure 2.27b). Large scale similarities in subsurface salinity changes across observational estimates point to decreasing (increasing) salinity in regions where salinity is lower (higher) than the global average, with freshening in subpolar regions and salinification in the subtropical gyres (Aretxabaleta et al., 2017; Cheng et al., 2020; Durack, 2015; Durack & Wijffels, 2010; Good et al., 2013; Skliris et al., 2014). Regional changes in salinity are assessed in Section 9.2.2.2.

In summary, it is *virtually certain* that since 1950 near-surface high salinity regions have become more saline, while low salinity regions have become fresher, and it is *very likely* that this extends to the ocean interior along ventilation pathways. Across basins, it is *very likely* that the Atlantic has become saltier and the Pacific and Southern oceans have freshened. The differences between high-salinity and low-salinity regions are linked to an intensification of the hydrological cycle (*medium confidence*).

[START FIGURE 2.27 HERE]

Figure 2.27: Changes in ocean salinity. Estimates of salinity trends using a total least absolute differences fitting method for (a) global near-surface salinity (SSS) changes and (b) global zonal mean subsurface salinity changes. Black contours show the associated climatological mean salinity (either near-surface (a) or subsurface (b)) for the analysis period (1950–2019). Both panels represent changes of Practical Salinity Scale 1978 [PSS-78], per decade. In both panels green denotes freshening regions and orange/brown denotes regions with enhanced salinities. 'x' marks denote non-significant changes. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.27 HERE]

2.3.3.3 Sea level

ACCEPTED VERSION SUBJECT TO FINAL EDITS

AR5 concluded based on proxy and instrumental data that the rate of global mean sea level (GMSL) rise since the mid-19th century was larger than the mean rate during the previous two millennia (*high confidence*). SROCC reported with *high confidence* that GMSL increases were 1.5 [1.1 to 1.9] mm yr^{-1} for 1902–2010 (with an acceleration rate between -0.002–0.019 mm yr^{-2}), 2.1 [1.8 to 2.3] mm yr^{-1} for 1970–2015, 3.2 [2.8 to 3.5] mm yr^{-1} for 1993–2015 and 3.6 [3.1 to 4.1] mm yr^{-1} for 2006–2015. AR5 reported that GMSL during the LIG was, over several thousand years, between 5 and 10 m higher than 1985–2004 (*medium confidence*) whereas SROCC concluded it was *virtually certain* that GMSL exceeded current levels (*high confidence*), and reached a peak that was *likely* 6–9 m higher than today, but did not exceed 10 m (*medium confidence*). AR5 concluded with *high confidence* that there were two intra-LIG GMSL peaks and that the millennial-scale rate during these periods exceeded 2mm yr^{-1}. AR5 had *high confidence* that GMSL during the MPWP did not exceed 20 m above present. Based on new understanding, SROCC placed the upper bound at 25 m but with *low confidence*.

The Earth was largely ice free during the EECO (Cramer et al., 2011; Miller et al., 2020, Section 9.6.2), and complete loss of current land ice reservoirs would raise GMSL by 65.6 ± 1.8 m (Farinotti et al., 2019; Morlighem et al., 2017; 2020). Given that GMSL change must be due to some combination of transient land ice growth and changes in terrestrial water storage, additional global mean thermosteric sea-level increase of 7 ± 2 m (Fischer et al., 2018) implies a peak EECO GMSL of 70–76 m (*low confidence*). Changes in ocean basin size driven by plate tectonics contributed a comparable amount to global mean geocentric sea level in the Eocene, but are definitionally excluded from GMSL assessment (Wright et al., 2020).

For the MPWP, several studies of coastal features have provided additional quantitative sea-level estimates of: 5.6–19.2 m from Spain (Dumitru et al., 2019), approximately 14 m from South Africa (Hearty et al., 2020), 15 m from the United States (Moucha and Ruetenik, 2017), and 25 m from New Zealand (Grant et al., 2019). Thus, consistent with SROCC, GMSL during the MPWP was higher than present by 5–25 m (*medium confidence*).

Reconstructions of GMSL from marine oxygen isotopes in foraminifera shells show variations of more than 100 m over intervals of 10–100 kyr during glacial-interglacial cycles of the Quaternary (McManus et al., 1999; Miller et al., 2020; Shackleton, 1987; Waelbroeck et al., 2002). Correction for past temperatures and a calibration for ice-volume changes implies uncertainty estimates of ± 10–13 m (1 SD) (Grant et al., 2014; Shakun et al., 2015; Spratt & Lisiecki, 2016). A recent marine oxygen-isotope-based GMSL reconstruction (Spratt and Lisiecki, 2016) agrees with previous reconstructions, while focusing on the past 800 kyr (Figure 2.28). It shows that GMSL during the Holocene was among the highest over this entire interval, and was surpassed only during the LIG (Marine Isotope Stage (MIS 5e)) and MIS 11 (*medium confidence*); however, relatively brief (about 2 kyr) highstands during other interglacial periods might be obscured by dating limitations.

Few sites globally have well-preserved MIS 11 sea-level indicators (Dutton et al., 2015). As reported in AR5, Raymo and Mitrovica (2012) used glacial isostatic adjustment models to correct the elevation of MIS 11 sea-level proxies from Bermuda and Bahamas to estimate a peak MIS 11 GMSL between 6 and 13 m above present-day. This agrees with the elevation of 13 ± 2 m for the MIS 11 subtidal–intertidal transition in South Africa (Roberts et al., 2012). A revised glacial isostatic adjustment at this location resulted in a peak GMSL estimate of 8–11.5 m (Chen et al., 2014). In light of these data, and the review by Dutton et al. (2015), the AR5 estimate of 6–13 m for MIS 11 remains the best available (*medium confidence*).

Recent studies have highlighted uncertainties in estimates of GMSL during the LIG, including the extent of GMSL variability (Capron et al., 2019). Vertical land motions (Austermann et al., 2017) are starting to be considered quantitatively (e.g., Stephenson et al., 2019), but are still bounded by large uncertainties. The distribution and thickness of pre-LIG ice sheets (Dendy et al., 2017; Rohling et al., 2017) and isostasy driven by sediment loading since the LIG (Pico, 2020) add further uncertainty. In light of these recent studies and previous assessments, there is *medium confidence* that peak GMSL during the LIG was *likely* between 5 and 10 m higher than modern. Relative sea-level estimates from some sites (e.g., Bahamas and Seychelles) report ephemeral, metre-scale fluctuations (Vyverberg et al., 2018). Different generations of LIG reef growth at other sites (e.g., Yucatan Peninsula, Western Australia) suggest the occurrence of sudden accelerations in

ACCEPTED VERSION SUBJECT TO FINAL EDITS

GMSL change (Blanchon et al., 2009; O'Leary et al., 2013). However, other sites (e.g., South Australia, Mediterranean), indicate that LIG sea level was substantially stable (Pan, Y-T. et al., 2018; Polyak et al., 2018). In addition, there are uncertainties in the interpretation of local relative sea level from some GMSL reconstructions (Barlow et al., 2018). Therefore, *low confidence* is assigned to any GMSL rate of change estimated within the LIG.

New geological proxies and glacial isostatic adjustment (GIA) modelling studies confirm that, at the LGM, GMSL was 125–134 m below present (Lambeck et al., 2014; Yokoyama et al., 2018). During the LDT, GMSL rose from approximately -120 m to -50 m, implying an average rate of about 10 mm yr^{-1} (Lambeck et al., 2014). The fastest rise occurred during Meltwater Pulse 1A, at about 14.6–14.3 ka (Deschamps et al., 2012; Sanborn et al., 2017), when GMSL rose by between 8 m and 15 m (*medium confidence*) (Liu J. et al., 2016) at an average rate of 24–44 mm yr^{-1}.

Recent GIA modelling studies tuned to both near- and far-field relative sea level (RSL) data yield MH GMSL estimates of -3.8 to -1.0 m (Lambeck et al., 2014; Peltier et al., 2015; Bradley et al., 2016; Roy and Peltier, 2017). Estimates from relatively stable locations where the effects of GIA are small and relatively insensitive to parameters defining Earth rheology, and where RSL is expected to approximate GMSL to within about 1 m (e.g., Milne & Mitrovica, 2008), suggest that RSL was between about -6 to 1.5 m at around 6 ka at multiple locations (Braithwaite et al., 2000; Camoin et al., 1997; Frank et al., 2006; Hibbert et al., 2018; Khan et al., 2017; Montaggioni & Faure, 2008; Vacchi et al., 2016). The assessment of GMSL change at 6 kyr is challenging considering the proportionately large GIA effect (Kopp et al., 2016a), insufficient resolution of marine geochemical proxies ($\delta^{18}O$, Mg/Ca) and uncertainties in the contribution of the Antarctic Ice Sheet during the MH (Section 2.3.2.4). The possibility that GMSL was at least somewhat higher than present cannot be excluded.

For the last 3 kyr, GMSL has been estimated from global databases of sea-level proxies, including numerous densely-sampled high-resolution salt-marsh records with decimetre scale vertical resolution and sub-centennial temporal resolution (Kopp et al., 2016b; Kemp et al., 2018a). Over the last about 1.5 kyr, the most prominent century-scale GMSL trends include average maximum rates of lowering and rising of -0.7 ± 0.5 mm yr^{-1} (2 SD) over 1020–1120 CE, and 0.3 ± 0.5 (2 SD) over 1460–1560, respectively. Between 1000 and 1750 CE, GMSL is estimated to have been within the range of about -0.11–0.09 m relative to 1900 (Kemp et al., 2018b). This was followed by a sustained increase of GMSL that began between 1820 and 1860 and has continued to the present day. New analyses demonstrate that it is *very likely* that GMSL rise over the 20th century was faster than over any preceding century in at least 3 kyr (Kopp et al., 2016a; Kemp et al., 2018a) (Figure 2.28).

[START FIGURE 2.28 HERE]

Figure 2.28: Changes in global mean sea level. (a) Reconstruction of sea-level from ice core oxygen isotope analysis for the last 800 kyr. For target paleo periods (CCB2.1) and MIS11 the estimates based upon a broader range of sources are given as box whiskers. Note the much broader axis range (200 m) than for later panels (tenths of metres). (b) Reconstructions for the last 2500 years based upon a range of proxy sources with direct instrumental records superposed since the late 19th century. (c) Tide-gauge and, more latterly, altimeter based estimates since 1850. The consensus estimate used in various calculations in Chapters 7 and 9 is shown in black. (d) The most recent period of record from tide-gauge and altimeter based records. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.28 HERE]

Since SROCC, two new tide gauge reconstructions of 20th century GMSL change have been published, although both rely upon CMIP models to varying degrees (Figure 2.28). Frederikse et al (2020) used a "virtual station" method and a probabilistic framework to estimate GMSL change and its uncertainties since 1900. Dangendorf et al (2019) combined a Kalman Smoother (Hay et al., 2015) with Reduced Space

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Optimal Interpolation (Church & White, 2011; Ray & Douglas, 2011) in an effort to better represent both the long-term GMSL change while preserving information on sea-level variability. In addition, new ensemble-based methods for quantifying GMSL change have been presented that account for both structural and parametric uncertainty (Palmer et al., 2021). Altimeter timeseries of GMSL change (Figure 2.28) have been extended to 2019/2020 but bias adjustments (Ablain et al., 2019; Beckley et al., 2017; Dieng et al., 2017; Legeais et al., 2020; Watson et al., 2015) did not change since SROCC.

Based on the ensemble approach of Palmer et al (2021) and an updated WCRP (2018) assessment (Figure 2.28) GMSL rose at a rate of 1.35 [0.78 to 1.92] mm yr^{-1} for the period 1901–1990 and 3.25 [2.88 to 3.61] mm yr^{-1} for 1993–2018 (*high confidence*). The average rate for 1901–2018 was 1.73 [1.28 to 2.17] mm yr^{-1} with a total rise of 0.20 [0.15 to 0.25] m (Table 9.5). The acceleration rate *very likely* is 0.094 [0.082 to 0.115] mm yr^{-2} for 1993–2018 (WCRP, 2018, updated), consistent with other estimates (Ablain et al., 2019; Chen X. et al., 2017; Legeais et al. 2020; Nerem et al., 2018; Watson et al., 2015; WCRP, 2018). For the period 1902–2010 the updated tide gauge reconstructions published since the SROCC also show a robust acceleration over the 20th century and the ensemble estimate of Palmer et al (2021) gives a value of 0.0053 [0.0042 to 0.0073] mm yr^{-2}, based on an unweighted quadratic fit.

In summary, GMSL is rising, and the rate of GMSL rise since the 20th century is faster than over any preceding century in at least the last three millennia (*high confidence*). Since 1901, GMSL has risen by 0.20 [0.15 to 0.25] m at an accelerating rate. Further back in time, there is *medium confidence* that GMSL was within –3.5–0.5 m (*very likely* range) of present during the MH, 5–10 m higher (*likely range*) during the LIG, and 5–25 m higher (*very likely* range) during the MPWP.

2.3.3.4 Ocean circulation

2.3.3.4.1 Atlantic Meridional Overturning circulation (AMOC)

AR5 concluded that there was no evidence of a trend in the AMOC during the period of instrumental observations. However, AR5 also stressed insufficient evidence to support a finding of change in the heat transport of the AMOC. SROCC assessed that there was emerging evidence in sustained observations, both in situ (2004–2017) and revealed from SST-based reconstructions, that the AMOC had weakened during the instrumental era relative to 1850–1900 (*medium confidence*), although there were insufficient data to quantify the magnitude of the weakening. SROCC also concluded with *low confidence* an increase of the Southern Ocean upper cell overturning circulation. SROCC also reported with *medium confidence* that the production of Antarctic Bottom Water had decreased since the 1950s consistent with a decreased lower cell overturning circulation, and potentially modulating the strength of the AMOC.

On multi-millennial timescales, proxy evidence indicates that the AMOC varied repeatedly in strength and vertical structure. During the last glacial period, particularly around the LGM, AMOC was estimated to be shallower than present, although there is continued debate about the magnitude of the shoaling (Gebbie, 2014; Lynch-Stieglitz et al., 2007), and whether this change was associated with a weaker overturning (Ritz et al., 2013; Menviel et al., 2017; Muglia et al., 2018). There are indications that substantial variations in AMOC were associated with abrupt climate changes during the glacial intervals, including Dansgaard-Oeschger and Heinrich events (14–70 ka) (Böhm et al., 2015; Henry et al., 2016; Lynch-Stieglitz, 2017; McManus et al., 2004). During these millennial-scale oscillations, weakened AMOC was associated with dramatic cooling in the northern hemisphere and warming in the southern hemisphere (Buizert et al., 2015; Henry et al., 2016), while hemispheric changes of opposite sign accompanied strengthened AMOC. After the final demise of the Laurentide ice sheet about 8 ka, the mean overall strength of AMOC has been relatively stable throughout the rest of the Holocene compared to the preceding 100 kyr (Hoffmann et al., 2018; Lippold et al., 2019). There are however indications of episodic variations in AMOC during the Holocene (Bianchi and McCave, 1999; Oppo et al., 2003; Thornalley et al., 2013; Ayache et al., 2018), and past interglacial intervals (Galaasen et al., 2014, 2020; Hayes et al., 2014; Huang et al., 2020; Mokeddem et al., 2014). Over the last 3 kyr, there are indications that AMOC variability was potentially linked to decreasing production of Labrador Sea Water (LSW), one of the water masses contributing to AMOC (Alonso-Garcia et al., 2017; McClymont et al., 2020; Moffa-Sánchez et al., 2019; Moffa-Sánchez & Hall, 2017).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Numerous proxy records collectively imply that AMOC is currently at its weakest point in the past 1.6 ka (Caesar et al., 2018, 2021; Rahmstorf et al., 2015; Thibodeau et al., 2018; Thornalley et al., 2018). Caesar et al. (2021) analyse a compilation of various available indirect AMOC proxies from marine sediments, in situ-based reconstructions and terrestrial proxies, which show a decline beginning in the late 19th century and over the 20th century superimposed by large decadal variability in the second half of the 20th century. Indirect reconstructions of AMOC components based on coastal sea level records in the western North Atlantic (Ezer, 2013; McCarthy et al., 2015; Piecuch, 2020) show an AMOC decline since the late 1950s, with only a short period of recovery during the 1990s.

However, other studies highlight that proxy records do not show such clear signals (Moffa-Sánchez et al., 2019), and the use of SST- and coastal sea level-based proxies of AMOC places uncertainties on these results (Jackson & Wood, 2020; Little et al., 2019; Menary et al., 2020). For instance, SSTs are additionally influenced by atmospheric and non-AMOC related ocean variability (Josey et al., 2018; Keil et al., 2020; Menary et al., 2020), while sea level responds to a variety of factors (e.g. atmospheric pressure and local winds) independent of the AMOC (Woodworth et al., 2014; Piecuch and Ponte, 2015; Piecuch et al., 2016). Finally, large decadal variability is present in many reconstructions and obscures estimation of the long-term trend over the 20th century (Caesar et al., 2021; Ezer, 2013; McCarthy et al., 2015; Thornalley et al., 2018; Yashayaev & Loder, 2016). It is also noted that the proxy reported AMOC decline, beginning in the late 19th century, is not supported by model-based evidence (Sections 3.5.4.1. and 9.2.3.l).

Since the 1980s, multiple lines of observational evidence for AMOC change exist. Ship-based hydrographic estimates of AMOC as far back as the 1980s show no overall decline in AMOC strength (Fu et al., 2020; Worthington et al., 2020). Direct indications from in-situ observations report a –2.5 ± 1.4 Sv change between 1993 and 2010 across the OVIDE section, superimposed on large interannual to decadal variability (Mercier et al., 2015). At 41°N and 26°N, a decline of –3.1 ± 3.2 Sv per decade and –2.5 ± 2.1 Sv per decade respectively has been reported over 2004–2016 (Baringer et al., 2018; Smeed et al., 2018). However, Moat et al. (2020) report an increase in AMOC strength at 26°N over 2009–2018. Recent time series of moored observations at 11ºS (Hummels et al., 2015), 34ºS (Meinen et al., 2018; Kersalé et al., 2020), and between 57 and 60ºN (Lozier et al., 2019a) are currently too short to permit robust conclusions about changes. The directly observed AMOC weakening since 2004, while significant, is over too short a period to assess whether it is part of a longer term trend or dominated by decadal-scale internal variability (Smeed et al., 2014; Collins et al., 2019; Moat et al., 2020). Notably an increase and subsequent decline in the 1990s is present in estimates of AMOC and associated heat transport constructed from reanalyses or auxiliary data (Frajka-Williams, 2015; Jackson & Wood, 2020; Jackson et al., 2016; Trenberth & Fasullo, 2017) (Section 9.2.3.1).

Repeated full depth in situ measurements report that deep convection - a major driver for AMOC - has recently returned to the Labrador Sea (particularly in 2015; Rhein et al., 2017; Yashayaev & Loder, 2016), and Irminger Sea (de Jong et al., 2018; de Jong & de Steur, 2016; Gladyshev et al., 2016) following an extended period with weak convection since 2000. An associated strengthening of the outflow from the Labrador Sea has not been observed (Zantopp et al., 2017; Lozier et al., 2019b), while strengthening of the AMOC is tentative (Desbruyères et al., 2019; Moat et al., 2020). A long-term increase of the upper overturning cell in the Southern Ocean since the 1990s can be assessed with *low confidence*, and there is *medium confidence* of a decrease in Antarctic bottom water (AABW) volume and circulation, which has potential implications for the strength of the AMOC (Section 9.2.3.2).

In summary, proxy-based reconstructions suggested that the AMOC was relatively stable during the past 8 kyr (*medium confidence*), with a weakening beginning since the late 19th century (*medium confidence*), but due to a lack of direct observations, *confidence* in an overall decline of AMOC during the 20th century *is low*. From mid-2000s to mid-2010s, the directly observed weakening in AMOC *(high confidence)* cannot be distinguished between decadal-scale variability or a long-term trend (*high confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.3.3.4.2 Western boundary currents and inter-basin exchanges

Both AR5 and SROCC reported that western boundary currents (WBCs) have undergone an intensification, warming and poleward expansion, except for the Gulf Stream and the Kuroshio, but did not provide confidence statements. AR5 reported with *medium* to *high confidence* intensification of the North Pacific subpolar gyre, the South Pacific subtropical gyre, and the subtropical cells, along with an expansion of the North Pacific subtropical gyre since the 1990s. It was pointed out that these changes are *likely* predominantly due to interannual-to-decadal variability, and in the case of the subtropical cells represent a reversal of earlier multi-decadal change. SROCC concluded that it was *unlikely* that there has been a statistically significant net southward movement of the mean Antarctic Circumpolar Current (ACC) position over the past 20 years, in contrast to AR5, where this change had been assessed with *medium confidenc*e.

The intensity of the Kuroshio current system in the northwest Pacific varied in conjunction with the glaciation cycles over the last 1 Myr, with some limited glacial-interglacial variability in position (Jian et al., 2000; Gallagher et al., 2015). The Agulhas current has strengthened substantially during the warming associated with deglaciations of the past 1 Myr (Peeters et al., 2004; Bard and Rickaby, 2009; Martínez-Méndez et al., 2010; Marino et al., 2013; Ballalai et al., 2019). According to sediment core analyses, the Agulhas leakage varied by about 10 Sv during major climatic transitions over the past 640 kyr (Caley et al., 2014). Available data suggests that there was relatively little change in the net flow of the ACC in the LGM, with no consensus on the sign of changes (Lamy et al., 2015; Lynch-Stieglitz et al., 2016; McCave et al., 2013), except at one location at the northern edge of the Drake Passage where a 40% decrease of transport had been reported (Lamy et al., 2015). Longer time series from the northern entrance to Drake Passage suggest a consistent transport variability of 6–16% through glacial climate cycles, with higher current speeds during interglacial times and reduced current speeds during glacial intervals (Toyos et al., 2020). Inferred variability in the size and strength of the North Atlantic subpolar gyre was substantial, and included rapid changes on millennial time scales during both interglacial and glacial intervals over the last 150 kyr (Born and Levermann, 2010; Mokeddem et al., 2014b; Irvalı et al., 2016; Mokeddem and McManus, 2016). North Atlantic – Arctic exchange has also varied in the past, with indications of an increasing inflow of Atlantic waters into the Arctic during the late Holocene (Ślubowska et al., 2005) with an acceleration to the recent inflow that is now the largest of the past 2 kyr (Spielhagen et al., 2011).

A latitudinal shift of subtropical/subpolar gyres on the order of 0.1 ± 0.04° per decade is derived by an indirect method using remote sensing data during 1993–2018 (Yang H. et al., 2020). Direct observations show a systematic poleward migration of WBCs (Bisagni et al., 2017; Wu L. et al., 2012; Yang H. et al., 2016, 2020). However, they do not support an intensification of WBCs, with a weakening, broadening, or little change reported for the Kuroshio (Collins et al., 2019; Wang & Wu, 2018; Wang et al., 2016), Gulf Stream (Andres et al., 2020; Collins et al., 2019; Dong et al., 2019; McCarthy et al., 2018), Agulhas (Beal and Elipot, 2016; Elipot and Beal, 2018) and East Australian (Sloyan and O'Kane, 2015) currents. The Gulf Stream has recently reversed a long-term poleward migration (Bisagni et al., 2017). Multidecadal variability of the strength and position of WBCs (Bisagni et al., 2017; Hsin, 2015; McCarthy et al., 2018) and short records from direct observations obscure the detection of any long-term trends (Yang H. et al., 2020).

The Pacific to Arctic exchange at the Bering Strait plays a minor role in the total Arctic exchange with the global ocean, which has increased from 0.8 Sv to 1.0 Sv over 1990–2015 (Woodgate, 2018). For Atlantic-Arctic exchange, major branches of Atlantic Water inflow from the North Atlantic into the Arctic across the Greenland-Scotland Ridge have remained stable since the mid-1990s (Berx et al., 2013; Hansen et al., 2015; Jochumsen et al., 2017; Østerhus et al., 2019), with only the smaller pathway of Atlantic Water north of Iceland showing a strengthening trend during 1993–2018 (Casanova-Masjoan et al., 2020), but with associated heat transport strengthening through the 1990s (Rossby et al., 2020; Tsubouchi et al., 2021). The Arctic outflow remained broadly stable from the mid-1990s to the mid 2010 (Osterhus et al., 2019). The heat and mass transport of the Indonesian throughflow (ITF) shows substantial variability at seasonal to decadal time scales (Feng M. et al., 2017, 2018; Li M. et al., 2018; Liu Q.-Y. et al., 2015; Sprintall et al., 2019; Susanto & Song, 2015; Xie T. et al., 2019; Zhuang et al., 2013). Liu et al. (2015) reported an increasing trend in the ITF geostrophic transport of 1 Sv per decade over 1984–2013, consistent with direct estimates (Sprintall et al., 2014), and results from reanalyses (Li et al., 2018), and this appears to be linked to multi-decadal scale variability rather than a long-term trend (England et al., 2014; Kosaka & Xie, 2013; Lee S.-K.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

et al., 2015). Southern Ocean circulation changes are assessed in SROCC (Meredith et al., 2019), and are confirmed and synthesized in Section 9.2.3.2 which shows that there is no indication of ACC transport change, and that it is *unlikely* that the mean meridional position of the ACC has moved southward in recent decades.

In summary, over the past 3–4 decades, the WBC strength is highly variable (*high confidence*), and WBCs and subtropical gyres have shifted poleward since 1993 (*medium confidence*). Net Arctic Ocean volume exchanges with the other ocean basins remained stable over the mid-1990s to the mid-2010s (*high confidence*). There is *high confidence* that the ITF shows strong multi-decadal scale variability since the 1980s.

2.3.3.5 Ocean pH

AR5 assessed with *high confidence* that the pH of the ocean surface has decreased since preindustrial times, primarily as a result of ocean uptake of CO_2. SROCC concluded that the global ocean absorbed 20–30% of total CO_2 emissions since the 1980s, with *virtually certain* ocean surface pH decline. The SROCC assessed a rate of surface pH decline of 0.017–0.027 pH units per decade across a range of time series of pH observations longer than 15 years. The decline in surface open ocean pH was assessed by SROCC as having *very likely* already emerged from background natural variability for more than 95% of the global surface open ocean.

Understanding of changes in surface pH at paleo time-scales has increased since AR5 (Anagnostou et al., 2020; Clarkson et al., 2015; Foster & Rae, 2016; Gutjahr et al., 2017; Harper et al., 2020; Henehan et al., 2019; Müller et al., 2020; Sosdian et al., 2018; Zeebe et al., 2016). Over the last 65 million years there have been several intervals when the pH of surface waters varied concurrently with climate change such as during the PETM, EECO, and MCO (Figure 2.29a) (Section 5.3.1.1). However, only during the PETM is the change sufficiently well-constrained to allow for a direct comparison with recent and current trends (Turner, 2018). This event was associated with profound perturbations of the global carbon cycle, ocean warming, deoxygenation and a surface ocean pH decrease *likely* ranging from 0.15 to 0.30 units (Penman et al., 2014; Gutjahr et al., 2017; Babila et al., 2018) - a rate that was *likely* at least an order of magnitude slower than today (Cui et al., 2011; Bowen et al., 2015; Frieling et al., 2016; Zeebe et al., 2016; Gutjahr et al., 2017; Kirtland Turner, 2018; Gingerich, 2019).

[START FIGURE 2.29 HERE]

Figure 2.29: Low latitude surface ocean pH over the last 65 million years. (a) Low-latitude (30°N–30°S) surface ocean pH over the last 65 million years, reconstructed using boron isotopes in foraminifera. (b) as (a) but for the last 3.5 million years. Double headed arrow shows the approximate magnitude of glacial-interglacial pH changes. (c) Multisite composite of surface pH. In a)-c), uncertainty is shown at 95% confidence as a shaded band. Relevant paleoclimate reference periods (CCB2.1) have been labelled. Period windows for succeeding panels are shown as horizontal black lines in a) and b). (d) Estimated low-latitude surface pH from direct observations (BATS, HOT) and global mean pH (65°S–65°N) from two indirect estimates (CMEMS, OCEAN-SODA). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.29 HERE]

Paleo evidence suggests that surface ocean pH has gradually increased over the last 50 Myr (Anagnostou et al., 2016; 2020; Sosdian et al., 2018) (Figure 2.29a). Global mean surface pH values as low as observed during recent decades are uncommon in the last 2 Myr (Figure 2.29b) (Chalk et al., 2017; Dyez et al., 2018; Martínez-Botí et al., 2015a; Sosdian et al., 2018), and have not been experienced in at least the last 25 kyr (Figure 2.29c) (Ezat et al., 2017; Foster, 2008; Gray et al., 2018; Henehan et al., 2013; Kirschke et al., 2013; Martínez-Botí et al., 2015a; Naik et al., 2015; Palmer et al., 2010; Palmer & Pearson, 2003; Shao et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2019). The magnitude of pH change during the Pleistocene glacial-interglacial cycles was 0.1–0.15 pH units - similar to recent changes in the modern era (Figure 2.29c) (Hönisch et al., 2009; Chalk et al., 2017; Shao et al., 2019) (Section 5.3.1.2). Maximum rates of pH change during the LDT, inferred from changes in atmospheric CO_2 recorded in ice cores (Marcott et al., 2014b) and the established relationships between pH and CO_2 changes and the boron isotope proxy (Hain et al. 2018), reached -0.02 pH units per century at about 11.7 ka, about 14.8 ka and about 16.3 ka, as previously sequestered CO_2 was transferred from the ocean interior to the subsurface ocean (Jaccard et al., 2016; Martínez-Botí et al., 2015a; Rae et al., 2018).

Since the 1980s, the global ocean has experienced a decline in surface pH of 0.016 ± 0.006 pH units per decade based on indirect pH products (Figure 2.29d) (Gehlen et al., 2020; Hurd et al., 2018; IPCC, 2019; Lauvset et al., 2015) that agrees with the decline of 0.017–0.025 pH units per decade assessed in SROCC from direct time-series measurements of pH. Section 5.3.2.2 assesses a decline that ranges from 0.01 to 0.026 pH units per decade for the tropical and subtropical open ocean areas, and 0.003–0.026 pH units per decade for the polar and subpolar open ocean regions by using time series and ship-based datasets from the surface ocean CO_2 measurement network (Bakker et al., 2016; Gehlen et al. 2020; Gregor & Gruber, 2021). There is general consensus that global surface ocean pH trends over the past two decades have exceeded the natural background variability (Bindoff et al., 2019; Gehlen et al., 2020; Lauvset et al., 2015). However, for some areas sparse data coverage, and large year-to-year variations hinders the detection of long-term surface ocean pH trends; for example in the Southern Ocean (Bindoff et al., 2019; Lauvset et al., 2015) and in the Arctic Ocean (Bindoff et al., 2019; Lauvset et al., 2015; Meredith et al., 2019).

For subsurface pH changes, estimates arise from direct ship measurements from repeated hydrography programs (Carter et al., 2019), indirect estimates of pH through calcite and aragonite saturation horizons (Osborne et al., 2020; Ross et al., 2020), and the very recent biogeochemical Argo floats equipped with pH sensors (Claustre et al., 2020). Global subsurface pH has decreased over the past 20–30 years, with signals observed to at least 1000 m depths (Lauvset et al., 2020). Global findings are supplemented by regional findings from the Pacific Ocean (Carter et al., 2019; Ross et al., 2020); the South Atlantic (Salt et al., 2015) and Southern Ocean (Jones et al., 2017); the North Atlantic Ocean and along the AMOC (Woosley et al., 2016; Perez et al., 2018), the Arctic Ocean (Qi et al., 2017) and marginal seas (Chen C.-T. A. et al., 2017). Further details are given in Section 5.3.3.1.

To conclude, it is *virtually certain* that surface open ocean pH has declined globally over the last 40 years by 0.003–0.026 pH per decade, and a decline in the ocean interior has been observed in all ocean basins over the past 2–3 decades (*high confidence*). A long-term increase in surface open ocean pH occurred over the past 50 Myr (*high confidence*), and surface open ocean pH as low as recent times is uncommon in the last 2 Myr (*medium confidence*). There is *very high confidence* that open ocean surface pH is now the lowest it has been for at least 26 kyr and current rates of pH change are unprecedented since at least that time.

2.3.3.6 Ocean deoxygenation

SROCC concluded that there has *very likely* been a net loss of oxygen over all ocean depths since the 1960s linked to global ocean deoxygenation at a range of 0.3–2.0%, and that the oxygen levels in the global upper 1000 m of the ocean had decreased by 0.5–3.3% during 1970–2010 (*medium confidence*), alongside an expansion of oxygen minimum zones (OMZ) by 3–8%. For the surface ocean (0–100 m) and the thermocline at 100–600 m, the *very likely* range of oxygen decline was assessed to be 0.2–2.1% and 0.7–3.5%, respectively. Multidecadal rates of deoxygenation showed variability throughout the water column and across ocean basins (*high confidence*).

Since AR5 evidence for changes in oxygen content based on new proxy reconstructions has increased (Anderson et al., 2019; Gottschalk et al., 2016, 2020; Hoogakker et al., 2015, 2018). Paleo records point to past periods of reduced oceanic oxygen levels during the late Permian (about 250 Ma), the Jurassic and Cretaceous (180–100 Ma), alongside associated global scale disturbances of the global carbon cycle. Emerging studies for the Cenozoic Era suggest more stable ocean oxygenation conditions throughout the interval on million-year time scales (Wang X. et al., 2016). Sedimentary proxy data indicate, however, that the seemingly stable Cenozoic was punctuated by transient, widespread deoxygenation during the PETM

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(Dickson et al., 2012; Winguth et al., 2012; Remmelzwaal et al., 2019), with parts of the ocean reaching anoxic levels (Yao et al., 2018) (Section 5.3.1.1). Since the LGM, there was an overall emergence and expansion of low-oxygen waters into the ocean intermediate depths as a result of rapid warming and a reorganization of the global overturning circulation (Galbraith and Jaccard, 2015). The maximum expansion of oxygen-depleted waters during the LDT occurred coincidently with rapid warming in the NH at 14.7–12.9 ka (Hoogakker et al., 2018; Jaccard & Galbraith, 2012; Moffitt et al., 2015). Deep (> 1500m) ocean oxygen levels increased by 100–150 μmol kg^{-1} since the LGM, reaching modern oxygen levels at about 10 ka (Anderson et al., 2019; Gottschalk et al., 2016; Hoogakker et al., 2015) (Section 5.3.1.2).

New findings for ocean oxygen content since SROCC are limited to regional scale assessments. The magnitude of change is difficult to compare across regions to arrive at a global assessment due to differences in depth range, time period, baseline climatology, methodology, and particularly the use of different units. To facilitate comparisons, data are presented as change per decade, and conversions of the SROCC global mean percentage of oxygen decline estimates are provided as a loss of 3.2 μmol kg^{-1} in the upper 1000 m of the global ocean (1.93%), and 2.0 μmol kg^{-1} (0.8 μmol kg^{-1} per decade) in the upper 1000 m of the global ocean (1.93%), and 2.0 μmol kg^{-1} (0.5 μmol kg^{-1} per decade) in the entire water column (1.15%) between 1970 and 2010 (Bindoff et al., 2019). Oxygen change also shows decadal variability (Ito et al., 2016; Stramma et al., 2020) that can influence estimates of trends.

Subsurface (100–400 m) oxygen in the California Current system is estimated to have declined by 24 ± 2 μmol kg^{-1} (1.0 μmol kg^{-1} per decade) between 1993 and 2018, a rate similar to the global upper 1000 m average (Bindoff et al. 2019). In some locations, however, the magnitude of oxygen loss substantially exceeds global averages (Queste et al., 2018; Bronselaer et al., 2020; Cummins and Ross, 2020; Stramma et al., 2020). For example, a decline in oxygen content of 11.7 ± 3.5% in the upper 4000 m, including a decline of 20.4 ± 7.2% in the upper 1550 m, is reported in the North Pacific over the period 1958–2018 (Cummins and Ross, 2020) (equivalent to 2.3 μmol kg^{-1} per decade in the upper 1550 m and 2.0 μmol kg^{-1} $decade^{-1}$ throughout the 4000 m water column). In some regions of the Southern Ocean south of 65°S oxygen in the upper 2000 m has declined by 60 μmol kg^{-1} (~52 μmol kg^{-1} per decade) based on comparisons of 2014–2019 and 1985–2005 observations (Bronselaer et al., 2020). Within some OMZs regions of the Indian ocean, oxygen has declined from 6–12 to < 2 μmol kg^{-1} between the 1960s and 2015–2016 (Bristow et al., 2017; Naqvi et al., 2018; Queste et al., 2018).

Findings since SROCC provide further support that the volume of severely oxygen-depleted water has expanded in some locations of the global ocean (Section 5.3.3.2). For example, vertical expansion of low oxygen zones is reported in the North Pacific at a rate of 3.1 ± 0.5 m yr^{-1} (Ross et al., 2020), and suboxic waters have increased by 20% at a rate of about 19 m per decade from 1982–2010 in the Arabian Sea (Naqvi et al., 2018; Lachkar et al., 2019), and expanded off the coast of Mexico (Sánchez-Velasco et al., 2019).

In summary, episodes of widespread and long-lasting (100 ka scales) open-ocean deoxygenation were related to warm climate intervals of the Permian-Cretaceous, with conditions becoming generally better oxygenated as the climate cooled over the course of the Cenozoic (*high confidence*). The largest expansions of oxygen depleted waters over the past 25 ka were strongly linked to rapid warming rates (*medium confidence*). Open-ocean deoxygenation has occurred in most regions of the open ocean during the mid- 20th to early 21st centuries (*high confidence*), and shows decadal variability (*medium confidence*). Evidence further confirms SROCC that OMZs are expanding at many locations (*high confidence*).

2.3.4 Biosphere

This section is limited to a few biological indicators to demonstrate the close links between the biosphere and physical forcing. In selecting the indicators, we focussed on those (i) that are observable at large (global) spatial scales and over long (two decades or more) temporal scales, using standardised and consistent procedures; and (ii) those that are illustrative of the influence of the physical system on the biological realm. Chapters 2 and 3 of WGII AR6 undertake a more holistic assessment of biospheric impacts.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2.3.4.1 Seasonal Cycle of CO_2

AR5 noted that because CO_2 uptake by photosynthesis occurs only during the growing season, the greater land mass in the NH imparts a characteristic 'sawtooth' seasonal cycle in atmospheric CO_2. SRCCL similarly stated that due to strong seasonal patterns of growth, NH terrestrial ecosystems are largely responsible for the seasonal variations in global atmospheric CO_2 concentrations. Neither AR5 nor SRCCL made a confidence statement about observed changes in the amplitude of the seasonal cycle of CO_2.

In situ observations of CO_2 generally depict a rising amplitude of the seasonal cycle over the past half century, especially north of about 45°N (Figure 2.30). For example, an amplitude increase of 6 ± 2.6% per decade has been observed at the Barrow surface observatory in Alaska over 1961–2011 (Graven et al., 2013), with slightly slower increases thereafter. Aircraft data north of 45°N exhibit an amplitude increase of 57 ± 7% at 500 mb versus an increase of 26 ± 18% for 35°N–45°N between field campaigns in 1958–1961 and 2009–2011 (Graven et al., 2013b). Increases in amplitude for the period 1980–2012 are apparent at eight surface observatories north of 50°N (Piao et al., 2018), related primarily to a larger drawdown in June and July. Trends in seasonal cycle amplitude at lower latitudes are smaller (if present at all); for instance, the increase at the Mauna Loa observatory in Hawaii since the early 1960s is only about half as large as at Barrow (Graven et al., 2013a), and only one other low-latitude observatory has a significant increase from 1980–2012 (Piao et al., 2018). There is a weak signal of an increase in amplitude at the Sinhagad observatory in western India in recent years (Chakraborty et al., 2020). Generally speaking, larger increases in the Arctic and boreal regions are indicative of changes in vegetation and carbon cycle dynamics in northern ecosystems (Forkel et al., 2016), though increased carbon uptake can also result from other factors such as warmer- and wetter-than-normal conditions.

Recent satellite-based, global-scale estimates of seasonal variations in atmospheric CO_2 for the period 2003–2018 show that the seasonal variations in the SH are out of phase with those in the NH (Reuter et al., 2020), which is consistent with the phenological shifts in primary productivity between hemispheres. The net effect of the phase shift between the two hemispheres is to dampen the amplitude of the global average seasonal cycle. These integrated results also show that the amplitude of the oscillations has been increasing in the SH, from about 2009, but comparison with data from Baring head suggests that periods of high seasonal oscillation had occurred at that location in the SH prior to 1995.

[START FIGURE 2.30 HERE]

Figure 2.30: Changes in the amplitude of the seasonal cycle of CO_2. (a) Observed peak-to-trough seasonal amplitude given by the day of year of downward zero crossing, of CO_2 concentration at Barrow (71°N, blue) and Mauna Loa (20°N, black). Seasonal CO_2 cycles observed at (b) Barrow and (c) Mauna Loa for the 1961–1963 or 1958–1963 and 2017–2019 time periods. The first six months of the year are repeated. Reprinted with permission from AAAS. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.30 HERE]

In summary, there is *very high confidence* that the amplitude of the seasonal cycle of atmospheric CO_2 has increased at mid-to-high NH latitudes since the early 1960s. The observed increase is generally consistent with greater greening during the growing season and an increase in the length of the growing season over the high northern high latitudes. Similarly, globally-integrated results from the SH also show an increase in seasonal amplitude of atmospheric CO_2 signal, from around 2009 to 2018 (*low confidence*).

2.3.4.2 Marine biosphere

2.3.4.2.1 Large-scale distribution of marine biota

SROCC pointed out that long-term global observations of many key ocean variables, including

ACCEPTED VERSION SUBJECT TO FINAL EDITS

phytoplankton, have not reached the density and accuracy necessary for detecting change. But SROCC noted the good comparability between short time-scale single-sensor ocean-colour products and a longer time-scale, climate-quality time series of multi-sensor, inter-sensor-bias-corrected, and error characterised, global data on chlorophyll-a concentration in the surface layers of the ocean. With respect to oligotrophic gyres, AR5 WGII concluded that the oligotrophic subtropical gyres of the Atlantic and Pacific Oceans are expanding and that they indicate declining phytoplankton stocks in these waters (*limited evidence, low agreement*). With respect to distributions of marine organisms, AR5 WGII reported range shifts of benthic, pelagic, and demersal species and communities (*high confidence*), though the shifts were not uniform.

Phytoplankton are responsible for marine primary production through photosynthesis; they are a major player in the ocean carbon cycle. They have a high metabolic rate, and respond fast to changes in environmental conditions (light, temperature, nutrients, mixing), and as such, serve as a sentinel for change in marine ecosystems. Concentration of chlorophyll-a, the major photosynthetic pigment in all phytoplankton, is often used as a measure of phytoplankton biomass. As primary producers, they are also food for organisms at higher trophic levels. The multi-sensor time series of chlorophyll-a concentration has now been updated (Sathyendranath et al., 2019) to cover 1998–2018. Figure 2.31 shows that global trends in chlorophyll-a for the last two decades are insignificant over large areas of the global ocean (von Schuckmann et al., 2019), but some regions exhibit significant trends, with positive trends in parts of the Arctic and the Antarctic waters (>3% yr^{-1}), and both negative and positive trends (within ± 3% yr^{-1}) in parts of the tropics, subtropics and temperate waters. The interannual variability in chlorophyll-a data in many regions is strongly tied to indices of climate variability (Section 2.4, Annex IV) and changes in total concentration are typically associated with changes in phytoplankton community structure (e.g., Brewin et al., 2012; Racault et al., 2017a). Variability in community structure related to El Niño has, in turn, been linked to variability in fisheries, for example in the catch of anchovy (*Engraulis ringens*) in the Humboldt current ecosystem (Jackson et al., 2011).

[START FIGURE 2.31 HERE]

Figure 2.31: Phytoplankton dynamics in the ocean. (a) Climatology of chlorophyll-a concentration derived from ocean-colour data (1998–2018); (b) Linear trends in chlorophyll concentration. Trends are calculated using OLS regression with significance assessed following AR(1) adjustment after Santer et al (2008c) ('x' marks denote non-significant changes). (c) Histogram of linear trends in chlorophyll concentration, after area weighting and with per-pixel uncertainty estimates based on comparison with in situ data. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.31 HERE]

Since AR5 WGII, analysis of a longer time series of ocean-colour data (1998–2012) has shown (Aiken et al., 2017) that the expansion of the low nutrient part of the North Atlantic oligotrophic gyre was significant, at 0.27 x 10^6 km^2 per decade, but that the rate was much lower than that reported earlier by Polovina et al. (2008). Furthermore, Aiken et al. (2017) reported no significant trend in the oligotrophic area of the South Atlantic Gyre. With the time series extended to 2016, von Schuckmann et al. (2018) reported that since 2007, there was a general decreasing trend in the areas of the North and South Pacific oligotrophic Gyres, while the North and South Atlantic oligotrophic Gyres remained stable, with little change in area, consistent with Aiken et al. (2017). The changing sign of trends in the areal extent of the oligotrophic gyres with increase in the length of the time series raises the possibility that these changes arise from interannual to multi-decadal variability. The time series of ocean-colour data is too short to discern any trend that might be superimposed on such variability.

Similarly, there is limited consistent and long-term information on large-scale distributions of marine organisms at higher trophic levels. But there are increased indications since AR5 and SROCC that the distributions of various higher trophic-level organisms are shifting both polewards and to deeper levels (Atkinson et al., 2019; Edwards et al., 2016; Haug et al., 2017; Lenoir et al., 2020; Pinsky et al., 2020), mostly consistent with changes in temperature. However observations also show a smaller set of counter-

ACCEPTED VERSION SUBJECT TO FINAL EDITS

intuitive migrations towards warmer and shallower waters, which could be related to changes in phenology and in larval transport by currents (Fuchs et al., 2020). There are also strengthening indications of greater representation by species with warm-water affinity in marine communities, consistent with expectations under observed warming (Burrows et al., 2019). There are indications that pre-1850 CE plankton communities are different from their modern counterparts globally (Jonkers et al., 2019). Indicators of geographical distributions of species (mostly from coastal waters) suggest that the rates at which some species are leaving or arriving at an ecosystem are variable, leading to changes in community composition (Blowes et al. 2019), with *likely* greater representation of warm-water species in some locations (Burrows et al., 2019).

In summary, there is *high confidence* that the latitudinal and depth limits of the distribution of various organisms in the marine biome are changing. There is *medium confidence* that there are differences in the responses of individual species relative to each other, such that the species compositions of ecosystems are changing. There is *medium confidence* that chlorophyll concentration in the surface shows weak negative and positive trends in parts of low and mid latitudes, and weak positive trends in some high-latitude areas. There is *medium confidence* that the large-scale distribution of the oligotrophic gyre provinces is subject to significant inter-annual variations, but *low confidence* in the long-term trends in the areal extent of these provinces because of insufficient length of direct observations.

2.3.4.2.2 Marine Primary production

SROCC expressed *low confidence* in satellite-based estimates of trends in marine primary production, citing insufficient length of the time series and lack of corroborating in situ measurements and independent validation time series. The report also cites significant mismatches in absolute values and decadal trends in primary production when different satellite-based products are compared.

Recent model-based results with assimilation of satellite data (Gregg and Rousseaux, 2019), show global annual mean marine primary production of around 38 (±1.13) PgC yr^{-1} over 1998–2015. This new result lies towards the low end of values reported in earlier, satellite-based, studies (range 36.5–67 PgC yr^{-1}, reported in Sathyendranath et al., 2020). Reconciling the results of Gregg & Rousseaux (2019) with earlier satellite-based studies leads to a mean of 47 (±7.8) PgC yr^{-1}. There is a strong correlation between interannual regional variability in marine primary production and climate variability (Gregg & Rousseaux, 2019; Racault et al., 2017b). The increase in primary production in the Arctic has been associated with retreating sea ice and with increases in nutrient supply and chlorophyll concentration (Lewis et al., 2020). Gregg and Rousseaux (2019) reported a decreasing trend in marine primary production, of -0.8 PgC (-2.1%) per decade globally. There is *low confidence* in this trend because of the small number of studies and the short length of the time series (<20 years).

In conclusion, there is *low confidence* because of the small number of recent studies and the insufficient length of the time series analysed that marine primary production is 47 (± 7.8) PgC yr^{-1}. A small decrease in productivity is evident globally for the period 1998–2015, but regional changes are larger and of opposing signs (*low confidence*).

2.3.4.2.3 Marine phenology

Phenology is the study of the timing of important events in the annual life cycle of organisms (plants or animals) (see also Annex VII: Glossary). AR5 WGII noted that the timing of various seasonal biological events in the ocean had advanced by more than four days per decade over the previous 50-year period and concluded that there was *high confidence* in observed changes in the phenological metrics of marine organisms. AR5 WGII further reported that, of those observations that showed a response, 81% of changes in phenology, distribution and abundance were consistent with anticipated responses to climate warming according to theoretical expectations, corroborated by updates in SROCC. The consequent current and future impacts on interactions between species, including competition and predator-prey dynamics, were noted with *high confidence*.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

There are additional indications that phenological metrics related to different species are changing, but not always in a similar manner. For example, many seabirds are breeding earlier, while others are breeding later (Sydeman et al., 2015). Planktonic organisms in the North Atlantic are also responding differently to each other when subjected to the same environmental changes (Edwards & Richardson, 2004). Furthermore, different factors could be responsible for triggering phenological responses in different stages in the life cycle of a single organism (Koeller et al., 2009). The shift in the distribution of many benthic invertebrates on the North-West Atlantic shelf, including some commercially-important shellfish, could be explained by phenology and larval transport and the shift and contraction of species range have been associated with higher mortality (Fuchs et al., 2020). Changes in phytoplankton phenological indicators globally (Racault et al., 2012; Sapiano et al., 2012) have been linked to indicators of climate variability, such as the multivariate ENSO Index (Racault et al., 2017a) with responses varying across ecological provinces of the ocean (Longhurst, 2007).

Phenological links between multiple components of an ecosystem have to be maintained intact, to retain system integrity. Since all higher pelagic organisms depend on phytoplankton for their food, either directly or indirectly, a match favours survival, and a mismatch is antagonistic to survival. Match represents synchonicity in the phenological events of both prey and predator. There are indications from ocean-colour data used in conjunction with fisheries data that the survival rate of various larger marine organisms depends on phenological metrics related to the seasonality of phytoplankton growth. Such links have been demonstrated, for example, for haddock (*Melanogrammus aeglefinus*) in the North-West Atlantic (Platt et al., 2003); northern shrimp in the North Atlantic (Koeller et al., 2009; Ouellet et al., 2011); sardine (*Sardinella aurita*) off the Ivory coast (Kassi et al., 2018); cod (*Gadus morhua*) and haddock (*Melanogrammus aeglefinus*) larvae in the North-West Atlantic (Trzcinski et al., 2013); and oil sardine (*Sardinella longiceps*) off the south-west coast of India. Borstad et al. (2011) showed that fledgling production rate of rhinoceros auklets (*Cerorhinca monocerata*) on a remote island in coastal north-eastern Pacific was related to seasonal values of chlorophyll-a biomass in the vicinity of the island.

In summary, new in situ data as well as satellite observations strengthen AR5 and SROCC findings that various phenological metrics for many species of marine organisms have changed in the last half century (*high confidence*), though many regions and many species of marine organisms remain under-sampled or even unsampled. The changes vary with location and with species (*high confidence*). There is a strong dependence of survival in higher trophic-level organisms (fish, exploited invertebrates, birds) on the availability of food at various stages in their life cycle, which in turn depends on phenologies of both (*high confidence*). There is a gap in our understanding of how the varied responses of marine organisms to climate change, from a phenological perspective, might threaten the stability and integrity of entire ecosystems.

2.3.4.3 Terrestrial biosphere

2.3.4.3.1 Growing season and phenology changes

AR5 WGII briefly discussed large-scale changes in the length of the growing season but made no confidence statement about observed trends. However, AR5 did conclude with *high confidence* that warming contributed to an overall spring advancement in the NH.

Recent in situ analyses document increases in the length of the thermal growing season (i.e., the period of the year when temperatures are warm enough to support growth) over much of the extratropical land surface since at least the mid-20th century. Over the NH as a whole, an increase of about 2.0 days per decade is evident for 1951–2018 (Dunn et al., 2020), with slightly larger increases north of 45°N (Barichivich et al., 2013). Over North America, a rise of about 1.3 days per decade is apparent in the United States for 1900–2014 (Kukal and Irmak, 2018), with larger increases after 1980 (McCabe et al., 2015); likewise, all ecozones in Canada experienced increases from 1950–2010 (Pedlar et al., 2015). Growing season length in China increased by at least 1.0 days per decade since 1960 (Xia et al., 2018) and by several days per decade in South Korea since 1970 (Jung et al., 2015). In general, changes in phenological indicators are consistent with the increase in growing season length documented by instrumental data (Parmesan and Hanley, 2015). Several long-term, site-specific records illustrate the unusualness of recent phenological changes relative to

ACCEPTED VERSION SUBJECT TO FINAL EDITS

interannual variability; for example, peak bloom dates for cherry blossoms in Kyoto, Japan have occurred progressively earlier in the growing season in recent decades, as have grape harvest dates in Beaune, France (Figure 2.32).

[START FIGURE 2.32 HERE]

Figure 2.32: Phenological indicators of changes in growing season. (a) cherry blossom peak bloom in Kyoto, Japan; (b) grape harvest in Beaune, France; (c) spring phenology index in eastern China; (d) full flower of Piedmont species in Philadelphia, USA; (e) Grape harvest in Central Victoria, Australia; (f) start of growing season in Tibetan Plateau, China. Red lines depict the 25-year moving average (top row) or the 9-year moving average (middle and bottom rows) with the minimum roughness boundary constraint of Mann (2004). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.32 HERE]

Changes in the length of the photosynthetically active growing season (derived from the Normalised Difference Vegetation Index (NDVI)) are also evident over many land areas since the early 1980s. Increases of about 2.0 days per decade are apparent north of 45°N since the early 1980s (centred over mid-latitude Eurasia and north-eastern North America), with indications of a reversal to a decline in season length starting in the early 2000s (Barichivich et al., 2013; Garonna et al., 2016; Liu Q. et al., 2016; Park et al., 2016; Zhao J. et al., 2015). Satellite-based records suggest that most NH regions have experienced both an earlier start and a later end to the growing season, a finding supported by ground-based data (Piao et al., 2020). A number of studies also capture increases in growing season length over the Canadian Arctic (Chen, 2016), Fennoscandia (Hogda et al., 2013), most of Europe (Garonna et al., 2014), and parts of sub-Saharan Africa (Vrieling et al., 2013).

The general consistency between in situ and satellite estimates over the NH is noteworthy given that many factors independently contribute to uncertainty in observed changes. For example, there is no universally accepted definition of growing season length across in situ analyses; some define the growing season as the period based on a temperature threshold (e.g., 5°C) whereas others use the frost-free period. Spatial and temporal coverage can also affect conclusions based upon in situ studies (Donat et al., 2013). For satellite analyses, uncertainties can be related to the satellite datasets themselves (e.g., satellite drift, sensor differences, calibration uncertainties, atmospheric effects); and to the methods for determining phenological metrics (e.g., start, end, and length of season) (Wang S. et al., 2016).

In summary, based on multiple independent analyses of in situ, satellite, and phenological data, there is *high confidence* that the length of the growing season has increased over much of the extratropical NH since at least the mid-20th century.

2.3.4.3.2 Terrestrial ecosystems

AR5 WGII concluded that many terrestrial species have shifted their geographic ranges in recent decades (*high confidence*). Similarly, SRCCL assessed that many land species have experienced range size and location changes as well as altered abundances over recent decades (*high confidence*). SROCC noted that species composition and abundance have markedly changed in high mountain ecosystems in recent decades (*very high confidence*).

Paleoclimate reconstructions document large-scale biome shifts from the deep past through the Holocene (e.g., Hoogakker et al., 2016). The northernmost location of the treeline is a representative indicator in this regard (Figure 2.34). During the MPWP, boreal forest extended to the Arctic coast, with the northernmost treeline being about 4° to 10° latitude further north than at present; temperate forests and grasslands were also shifted poleward (with reduced tundra extent), while savannahs and woodlands were more expansive in Africa and Australia at the expense of deserts (Salzmann et al., 2008, 2013; Sniderman et al, 2016; Andrae et

ACCEPTED VERSION SUBJECT TO FINAL EDITS

al., 2018) (Cross-Chapter Box 2.4 Figure 1b). During the LGM, tundra and steppe expanded whereas forests were globally reduced in extent (Binney et al., 2017; Prentice et al., 2000), the northern treeline being about 17° to 23° latitude south of its present day location in most areas. During the LDT, pervasive ecosystem transformations occurred in response to warming and other climatic changes (Nolan et al., 2018; Fordham et al., 2020). By the MH, North Africa had experienced a widespread conversion from grasslands to desert (Hoelzmann et al., 1998; Prentice et al., 2000; Sha, 2019), and the northernmost treeline had shifted poleward again to about 1° to 3° latitude north of its current location (Binney et al., 2009; MacDonald et al., 2000; Williams et al., 2011). Over the past half century, there has been an increase in the spatial synchrony of annual tree growth across all continents that is unprecedented during the past millennium (Manzanedo et al., 2020). Elevated rates of vegetation change in the Holocene are consistent with climate variability (Shuman et al., 2019), intensified human land use (Fyfe et al., 2015; Marquer et al., 2017c), and resulting increased ecosystem novelty (Finsinger et al., 2017; Burke et al., 2019).

Long-term ecological records capture extensive range shifts during the 20th and early 21st centuries (Lenoir & Svenning, 2015; Pecl et al., 2017). Research has been most extensive for North America and western Eurasia, with fewer studies for central Africa, eastern Asia, South America, Greenland, and Antarctica (Lenoir & Svenning, 2015). Most documented changes are toward cooler conditions - i.e., poleward and upslope (Lenoir et al., 2008; Harsch et al., 2009; Elmendorf et al., 2015; Parmesan and Hanley, 2015; Evans and Brown, 2017). Notably, a large, quasi-global analysis (Chen et al., 2011) estimated that many insect, bird, and plant species had shifted by 17 (± 3) km per decade toward higher latitudes and 11 (± 2) m per decade toward higher elevations since the mid-20th century, with changes in both the leading and trailing edges of species ranges (Rumpf et al., 2018). Over the past century, long-term ecological surveys also show that species turnover (i.e., the total number of gains and losses of species within an area) has significantly increased across a broad array of ecosystems (Dornelas et al., 2014; 2019), including undisturbed montane areas worldwide (Gibson-Reinemer et al., 2015). Despite global losses to biodiversity, however, most local assemblages have experienced a change in biodiversity rather than a systematic loss (Pimm et al., 2014). With increased species turnover, the novelty of contemporary communities relative to historical baselines has risen (Hobbs et al., 2009; Radeloff et al., 2015) due to greater spatial homogenization, mixtures of exotic and native species, altered disturbance regimes, and legacies of current or historic land use (Olden and Rooney, 2006; Schulte et al., 2007; Thompson et al., 2013; Goring et al., 2016). In general, terrestrial species have had lower rates of turnover than marine species (Dornelas et al., 2018; Blowes et al., 2019).

There are exceptions to the general pattern of poleward / upslope migration. For some species, various biotic and abiotic factors (such as precipitation and land use) supersede the physiological effects of temperature (Vanderwal et al., 2013; Gibson-Reinemer and Rahel, 2015; Ordonez et al., 2016; Scheffers et al., 2016; Lenoir et al., 2020). For other species, poleward migration is slower than expectations from the observed temperature increases. Trees are one such example because of their long lifespan and gradual maturity (Renwick and Rocca, 2015); in fact, poleward advance is only evident at about half of the sites in a large global dataset of treeline dynamics for 1900-present (Harsch et al., 2009b). Furthermore, the northernmost extent of treeline at present (roughly 73°N) is actually somewhat south of its location in the MH (MacDonald et al., 2008) despite an expanding growing season in the extratropical NH since the mid-20th century (Section 2.3.4.3.1).

Consistent with species range shifts, SRCCL noted that there have been changes in the geographical distribution of climate zones. Poleward shifts in temperate and continental climates are evident across the globe over 1950–2010, with decreases in the area (and increases in the average elevation) of polar climates (Chan and Wu, 2015). Zonal changes towards higher latitudes in winter plant hardiness regions are apparent since the 1970s over the central and eastern United States, with elevational changes also being important in the western united states (Daly et al., 2012). A clear northward shift in winter plant hardiness zones is detectable across western Canada since 1930, with somewhat lesser changes in the south eastern part of the country (McKenney et al., 2014). A northward migration of agro-climate zones is also evident over Europe since the mid-1970s (Ceglar et al., 2019). In addition, a shift toward more arid climate zones is apparent in some areas, such as the Asian monsoon region (Son and Bae, 2015) as well as parts of South America and Africa (Spinoni et al., 2015).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

In summary, there is *very high confidence* that many terrestrial species have shifted their geographic ranges poleward and/or upslope over the past century, with increased rates of species turnover. There is *high confidence* that the geographical distribution of climate zones has shifted in many parts of the world.

2.3.4.3.3 Global greening and browning

AR5 WGII briefly discussed changes in global vegetation greenness derived from satellite proxies for photosynthetic activity. Observed trends varied in their strength and consistency, and AR5 thus made no confidence statement on observed changes. SRCCL subsequently concluded that greening had increased globally over the past 2–3 decades (*high confidence*).

Vegetation index data derived from AVHRR and MODIS depicts increases in aspects of vegetation greenness (i.e., green leaf area and/or mass) over the past four decades (Piao et al., 2020). NDVI increased globally from the early 1980s through the early 2010s (Liu et al., 2015c). Pan et al. (2018a) found NDVI increases over about 70% of the Earth's vegetated surface through 2013, and Osborne et al. (2018) noted strong upward changes in NDVI in the circumpolar Arctic through 2016. Globally integrated Leaf Area Index (LAI) also rose from the early 1980s through at least the early 2010s (Zhu et al., 2016; Forzieri et al., 2017; Jiang et al., 2017; Xiao et al., 2017) and probably through near-present; for example, Chen et al. (2019) documented an LAI increase over one-third of the global vegetated area from 2000–2017. Although less frequently analysed for temporal trends, Fraction of Absorbed Photosynthetically Active Radiation (FAPAR) likewise increased over many global land areas (particularly China, India, and Eastern Europe) in the past two decades (Figure 2.33) (Forkel et al., 2014; Gobron, 2018; Keenan & Riley, 2018). There are also documented changes in specific vegetation types, such as a 7% rise in global tree cover for 1982–2016 (Song et al., 2018) and an expansion of shrub extent in the Arctic tundra over 1982–2017 (Myers-Smith et al., 2020). The increased greening is largely consistent with CO_2 fertilization at the global scale, with other changes being noteworthy at the regional level (Piao et al., 2020); examples include agricultural intensification in China and India (Chen et al., 2019; Gao et al., 2019) and temperature increases in the northern high latitudes (Kong et al., 2017; Keenan and Riley, 2018) and in other areas such as the Loess Plateau in central China (Wang et al., 2018). Notably, some areas (such as parts of Amazonia, central Asia, and the Congo basin) have experienced browning (i.e., decreases in green leaf area and/or mass) (Anderson et al., 2019; Gottschalk et al., 2016; Hoogakker et al., 2015). Because rates of browning have exceeded rates of greening in some regions since the late 1990s, the increase in global greening has been somewhat slower in the last two decades (Pan et al., 2018a).

[START FIGURE 2.33 HERE]

Figure 2.33: Satellite-based trends in Fraction of Absorbed Photosynthetically Active Radiation (per decade) for 1998–2019. Trends are calculated using OLS regression with significance assessed following AR(1) adjustment after Santer et al (2008c) ('x' marks denote non-significant trend). Unvegetated areas such as barren deserts (grey) and ice sheets (white) have no trend in FAPAR. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.33 HERE]

Global-scale linear trends differ substantially across products for the same periods and trend metrics used (Jiang et al., 2017). Several factors contribute to this large span in estimated changes. Remotely sensed vegetation products vary in their spatial and temporal completeness as well as resolution and are sensitive to contamination from atmospheric composition, clouds, snow cover, and anisotropy, as well as orbital changes and sensor degradations (de Jong et al., 2012; Zhu et al., 2016; Jiang et al., 2017; Xiao et al., 2017; Pan et al., 2018a). Ground-based measurements suitable for calibration and validation are scarce before 2000 (Xiao et al., 2017), and the recalibration of satellite records (e.g., as in from MODIS Collection 5 to 6) can affect trends (Piao et al., 2020). It is possible that the increase in greenness over 2000–2015 is larger than the increase in gross primary production (based on flux tower measurements and MODIS Collection 6 data) (Zhang L. et al., 2018). Land use changes and altered disturbance regimes (e.g. floods, fires, diseases) may

ACCEPTED VERSION SUBJECT TO FINAL EDITS

mask large-scale signals (Franklin et al., 2016). In addition, there is a plethora of models for the identification of phenological metrics from satellite data as well as a variety of statistical techniques for analysing historical changes (Wang et al., 2016).

In summary, there is *high confidence* that vegetation greenness (i.e., green leaf area and/or mass) has increased globally since the early 1980s. However, there is *low confidence* in the magnitude of this increase owing to the large range in available estimates.

2.3.5 Synthesis of evidence for past changes

Section 2.3 has assessed the observational evidence for changes in key indicators across the atmosphere, cryosphere, ocean and biosphere starting, where applicable, from paleoclimate proxy records and coming up to the present day. This synthesis serves as an assessment of the evidence for change across the climate system as represented by the instrumental record and its unusualness in the longer-term context. Building upon previous sections assessing the observational evidence for each key indicator individually, this section integrates the evidence across multiple indicators to arrive at a holistic and robust final assessment.

Climate has varied across a broad range of timescales (Figure 2.34). During the Cenozoic Era temperatures generally decreased over tens of millions of years, leading to the development of ice sheets. During the last two million years, climate has fluctuated between glacials and interglacials. Within the current Holocene interglacial and, with increasing detail in the CE, it is possible to reconstruct a history both of more indicators of the climate system and, with increasing fidelity, the rates of change. Solely for the last 150 years or so are instrumental observations of globally distributed climate indicators available. However, only since the late 20th century have observational systems attained essentially global monitoring capabilities. The direct observations point unequivocally to rapid change across many indicators of the climate system since the mid-19th century. These are all consistent in indicating a world that has warmed rapidly.

Assessing the long-term context of recent changes is key to understanding their potential importance and implications. The climate system consists of many observable aspects that vary over a very broad range of timescales. Some biogeochemical indicators of change such as atmospheric CO_2 concentrations and ocean pH have shifted rapidly and CO_2 concentrations are currently at levels unseen in at least 800 kyr (the period of continuous polar ice-core records) and *very likely* for millions of years. The GMST in the past decade is *likely* warmer than it has been on a centennially-averaged basis in the CE and *more likely than not* since the peak of the LIG. Many more integrative components of the climate system (e.g., glaciers, GMSL) are experiencing conditions unseen in millennia, whereas the most slowly responding components (e.g. ice-sheet extent, permafrost, tree line) are at levels unseen in centuries (*high confidence*). The rate at which several assessed climate indicators (e.g., GMSL, OHC, GSAT) have changed over recent decades is highly unusual in the context of preceding slower changes during the current post-glacial period (*high confidence*).

In summary, directly observed changes in the atmosphere, ocean, cryosphere and biosphere are unequivocal evidence of a warming world. Key climate indicators are now at levels not experienced for centuries to millennia. Since the late 19th century many indicators of the global climate system have changed at a rate unprecedented over at least the last two thousand years.

[START FIGURE 2.34 HERE]

Figure 2.34: Selected large-scale climate indicators during paleoclimate and recent reference periods of the Cenozoic Era. Values are based upon assessments carried out in this chapter, with *confidence* levels ranging from *low* to *very high*. Refer to Cross-Chapter Box 2.1 for description of paleoclimate reference periods and Section 1.4.1 for recent reference periods. Values are reported as either the *very likely* range (x to y), or best estimates from beginning to end of the reference period with no stated uncertainty (x → y), or lowest and highest values with no stated uncertainty (x ~ y). Temperature is global mean surface temperature. Glacier extent is relative and colour scale is inverted so that more extensive glacier extent is intuitively blue.

[START CROSS-CHAPTER BOX 2.4 HERE]

Cross-Chapter Box 2.4: The climate of the Pliocene (around 3 million years ago), when CO_2 concentrations were last similar to those of present day

Contributing Authors: Alan Haywood (UK), Darrell Kaufman (USA), Nicholas Golledge (New Zealand), Dabang Jiang (China), Daniel Lunt (UK), Erin McClymont (UK), Ulrich Salzmann (UK), Jessica Tierney (USA)

Throughout this Report, information about past climate states is presented in the context of specific climate variables, processes or regions. This Cross-Chapter Box focuses on a single paleoclimate reference period as an example of how proxy data, models and process understanding come together to form a more complete representation of a warm climate state that occurred during the relatively recent geologic past.

Introduction. The Pliocene Epoch is one of the best-documented examples of a warmer world during which the slow responding components of the climate system were approximately in balance with concentrations of atmospheric CO_2, similar to present (e.g., Haywood et al., 2016). It provides a means to constrain Earth's equilibrium climate sensitivity (Section 7.5.3) and to assess climate model simulations (Section 7.4.4.1.2). During the Pliocene, continental configurations were similar to present (Cross-Chapter Box 2.4 Figure 1a), and many plant and animal species living then also exist today. These similarities increase reliability of paleo-environmental reconstructions compared with those for older geological periods. Within the well-studied mid-Pliocene Warm Period (MPWP, also called the mid-Piacenzian Warm Period, 3.3–3.0 Ma), the interglacial period KM5c (3.212–3.187 Ma) has become a focus of research because its orbital configuration, and therefore insolation forcing, was similar to present (global mean insolation = –0.022 W m^{-2} relative to modern; Haywood et al., 2013), allowing for the climatic state associated with relatively high atmospheric CO_2 to be assessed with fewer confounding variables.

Major global climate indicators. During the KM5c interglacial, atmospheric CO_2 concentration was typically between 360 and 420 ppm (Section 2.2.3.1). New climate simulations of this interval from the Pliocene Model Intercomparison Project Phase 2 (PlioMIP2) show a multi-model mean global surface air temperature of 3.2°C [2.1–4.8] °C warmer than control simulations (Haywood et al., 2020; Cross-Chapter Box 2.4 Figure 1a). This is consistent with proxy evidence for the broader MPWP, which indicates that global mean surface temperature was 2.5°C–4.0°C higher than 1850–1900 (Section 2.3.1.1.1). Global mean sea level was between 5 and 25 m higher than present (Section 2.3.3.3). Geological evidence (Section 2.3.2.4) and ice-sheet modelling (Section 9.6.2) indicate that both the Antarctic and Greenland Ice Sheets were substantially smaller than present (Cross-Chapter Box 2.4 Figure 1c). Attribution of sea level highstands to particular ice sheet sources (Section 9.6.2) is challenging (DeConto & Pollard, 2016; Golledge, 2020), but improving (Berends et al., 2019; Grant et al., 2019).

Northern high latitudes. The latitudinal temperature gradient during the MPWP was reduced relative to present-day and the consistency between proxy and modelled temperatures has improved since AR5 (Section 7.4.4.1.2). Northern high latitude (> 60°N) SSTs were up to 7°C higher than 1850–1900 (Bachem et al., 2016; McClymont et al., 2020; Sánchez-Montes et al., 2020), and terrestrial biomes were displaced poleward (e.g., Dowsett et al., 2019) (Cross-Chapter Box 2.4, Figure 1b). Arctic tundra regions currently underlain by permafrost were warm enough to support boreal forests, which shifted northward by approximately 250 km in Siberia, and up to 2000 km in the Canadian Arctic Archipelago (Fletcher et al., 2017; Salzmann et al., 2013). The shift caused high-latitude surface albedo changes, which further amplified the Pliocene global warming (Zhang & Jiang, 2014). Vegetation changes in northeast Siberia indicate that MPWP summer temperatures were up to 6°C higher than present day (Brigham-Grette et al., 2013). Farther south, modern boreal forest regions in Russia and eastern North America were covered with temperate forests and grasslands, whereas highly diverse, warm-temperate forests with subtropical taxa were widespread in central

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and eastern Europe (Cross-Chapter Box 2.4, Figure 1). While seasonal sea ice was present in the North Atlantic and Arctic oceans, its winter extent was reduced relative to present (Knies et al., 2014; Clotten et al., 2018), and some models suggest that the Arctic was sea ice free during the summer (Feng et al., 2020; Howell et al., 2016).

Tropical Pacific. The average longitudinal temperature gradient in the tropical Pacific was weaker during the Pliocene than during 1850–1900 (Section 7.4.4.2.2). Changes in Pacific SSTs and SST gradients had far-reaching impacts on regional climates through atmospheric teleconnections, affecting rainfall patterns in western North America (Burls & Fedorov, 2017; Ibarra et al., 2018). The reduced zonal SST gradient has led some to propose that the Pliocene Pacific experienced a "permanent El Niño" state (Molnar and Cane, 2002; Fedorov, 2006). However, there is no direct geological evidence, nor support from climate models, that ENSO variability collapsed during the Pliocene. Although not located in the centre-of-action region for ENSO, Pliocene corals show temperature variability over 3–7 year timescales (Watanabe et al., 2011). In addition, a multi-model intercomparison indicates that ENSO existed, albeit with reduced variability (Brierley, 2015). Thus, there is *high confidence* that ENSO variability existed during the Pliocene.

Hydrological cycle. Vegetation reconstructions for the late Pliocene indicate regionally wetter conditions resulting in an expansion of tropical savannas and woodlands in Africa and Australia at the expense of deserts (Cross-Chapter Box 2.4, Figure 1b). PlioMIP2 climate models generally simulate higher rates of mean annual precipitation in the tropics and high latitudes, and a decrease in the subtropics, with a multi-model mean global increase of 0.19 mm day^{-1} [0.13–0.32 mm day^{-1}] relative to control simulations (Haywood et al., 2020) (Cross-Chapter Box 2.4, Figure 1a). Both simulations and *limited* proxy *evidence* indicate stronger monsoons in northern Africa, Asia, and northern Australia relative to present, but trends are uncertain in other monsoon regions (Huang X. et al., 2019; Li X. et al., 2018; Yang et al., 2018; Zhang et al., 2019). There is thus *medium confidence* that monsoon systems were stronger during the Pliocene. Simulations of MPWP climate show that global tropical cyclone intensity and duration increased during the MPWP (Yan et al., 2016); however, there is *low confidence* in this result because inter-model variability is high.

Summary. During the MPWP (3.3–3.0 Ma) the atmospheric CO_2 concentration was similar to present, and the slow-response, large-scale indicators reflect a world that was warmer than present. With *very high confidence*, relative to present, global surface temperature, sea level, and precipitation rate were higher, NH latitudinal temperature gradient was lower, and major terrestrial biomes expanded poleward. With *medium confidence* from proxy-based evidence alone (Section 2.3.2), combined with numerical modelling, analysis of the sea-level budget, and process understanding (Section 9.6.2), there is *high confidence* that cryospheric indicators were diminished. There is *medium confidence* that the Pacific longitudinal temperature gradient was weaker and monsoon systems were stronger.

[START CROSS-CHAPTER BOX 2.4, FIGURE 1 HERE]

Cross-Chapter Box 2.4, Figure 1: Climate indicators of the mid-Pliocene Warm Period (3.3–3.0 Ma) from models and proxy data. (a) Simulated surface air temperature (left) and precipitation rate anomaly (right) anomaly (relative to 1850–1900) from the Pliocene Model Intercomparison Project Phase 2 multi-model mean, including CMIP6 (n = 4) and non-CMIP6 (n = 12) models. Symbols represent site-level proxy-based estimates of sea-surface temperature for KM5c (n = 32), and terrestrial temperature (n = 8) and precipitation rate for the MPWP (n = 8). (b) Distribution of terrestrial biomes was considerably different during the Piacenzian Stage (3.6–2.6 Ma) (upper) compared with present-day (lower). Biome distributions simulated with a model (BIOME4) in which Pliocene biome classifications are based on 208 locations, with model-predicted biomes filling spatial gaps, and the present day, with the model adjusted for CO_2 concentration of 324 ppm. (c) Ice-sheet extent predicted using modelled climate forcing and showing where multiple models consistently predict the former presence or absence of ice on Greenland (n = 8 total) and Antarctica (n = 10 total). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END CROSS-CHAPTER BOX 2.4, FIGURE 1 HERE]

[END CROSS-CHAPTER BOX 2.4 HERE]

2.4 Changes in modes of variability

Modes of climate variability that are important for large-scale climate on interannual and longer timescales (Cross-Chapter Box 2.2) are assessed herein and defined and summarised in Annex IV. Though the modes of variability discussed here are assessed and classified on the basis of physical variables, it is important to recognise that the distribution and function of various components of the terrestrial and marine biospheres are modified in response to them.

2.4.1 Annular modes

2.4.1.1 Northern Annular Mode (NAM) / North Atlantic Oscillation (NAO)

AR5 reported that the shift towards a positive NAO, a mode of variability in the North Atlantic that is closely related to the hemispheric-scale NAM, from the 1950s to the 1990s was largely reversed by more recent changes (*high confidence*). Moreover, periods of persistent negative or positive NAO states observed during the latter part of the 20th century were not unusual, based on NAO reconstructions spanning the last half millennium (*high confidence*).

New multi-millennial-timescale NAO reconstructions are derived from marine and lake sediments, speleothems, tree rings and ice cores (Ortega et al., 2015; Faust et al., 2016; Sjolte et al., 2018). NAO variability over the past 8 kyr suggests the presence of a significant 1.5 kyr periodicity (Darby et al., 2012). Positive NAO conditions dominated during the MH, while the prevailing NAO sign during the early and late Holocene was negative according to most reconstructions (Brahim et al., 2019; Hernández et al., 2020; Olsen et al., 2012; Røthe et al., 2019). For the CE, reconstructions developed since AR5 indicate no dominant NAO phase during 1000–1300 CE (Baker et al., 2015; Hernández et al., 2020; Jones et al., 2014; Lasher & Axford, 2019; Ortega et al., 2015), with either negative (Baker et al., 2015; Faust et al., 2016; Mellado-Cano et al., 2019) or a more variable phase of the NAO (Jones et al., 2014; Ortega et al., 2015; Sjolte et al., 2018; Cook et al., 2019) between 1400 and 1850 CE. Several instrument-based NAO reconstructions extending back to the 17th and 18th centuries highlight the presence of multidecadal variations in the NAO phases (Cornes et al., 2013; Cropper et al., 2015), although these studies have limitations considering the seasonality of the centres of action and the locations of the stations used. Recent reconstructions of the large scale sea level pressure field yield more robust NAO analysis, showing a persistently negative NAO phase from the 1820s to the 1870s, with positive values dominating during the beginning of the 20th century followed by a declining trend over 1920–1970, with a recovery thereafter to a period of consistently high values between 1970 and the early 1990s (Delaygue et al., 2019; Mellado-Cano et al., 2019). Based on the evaluation of several NAO reconstructions for recent centuries, Hernández et al. (2020) highlighted that the strong positive NAO phases of the 1990s and early 21st century were not unusual.

The predominantly positive phase during the 1990s was followed by partial reversal and a tendency towards stronger variability in boreal winter NAM and NAO since the late 1990s (Hanna et al., 2018; Pinto & Raible, 2012). This is particularly evident in December NAO (Hanna et al., 2015) and NAM (Overland and Wang, 2015) indices, and is not unusual on multidecadal time scales (Woollings et al., 2018a). Since the 1990s, a statistically significant summer NAO decline was reported, which is, to a lesser extent, also evident in the winter NAO, linked to an enhanced blocking activity over Greenland (Hanna et al., 2015; 2016; Wachowicz et al., 2021). However, this was moderated by a persistent positive NAO values since 2015 (Annex IV 2.1). Based on observations and reanalysis datasets, multidecadal fluctuations were found for the NAM patterns: the Atlantic centre remained unchanged throughout 1920–2010, whereas the Pacific centre was stronger during 1920–1959 and 1986–2010 and weaker during 1960–1985 (Gong et al., 2018). Multidecadal changes were also observed in the position of the centres of action of the NAO (Moore et al., 2013; Zuo et al., 2016).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

In summary, positive trends for the NAM / NAO winter indices were observed between the 1960s and the early 1990s, but these indices have become less positive or even negative thereafter (*high confidence*). The NAO variability in the instrumental record was *very likely* not unusual in the millennial and multi-centennial context.

2.4.1.2 Southern Annular Mode (SAM)

AR5 concluded that it was *likely* that the SAM had become more positive since the 1950s and that this increase was unusual in the context of the prior 400 years (*medium confidence*). Both AR5 and SROCC reported statistically significant trends in the SAM during the instrumental period for the austral summer and autumn.

Several studies have attempted to reconstruct the evolution of the SAM during the Holocene using proxies of the position and strength of the zonal winds, although with no clear consensus regarding the timing and phase of the SAM (Hernández et al., 2020). The early Holocene was dominated by SAM positive phases (Moreno et al., 2018; Reynhout et al., 2019), consistent with increasing westerly wind strength (Lamy et al., 2010), with some reconstructions showing significant centennial and millennial variability but no consistent trend after 5 ka (Hernández et al., 2020). For the CE, enhanced westerly winds occurred over 0–1000 CE, as reflected in increased burning activity in Patagonia (Turney et al., 2016a) and tree ring records from southern New Zealand (Turney et al., 2016b), imply a predominantly positive SAM phase. Pollen records and lake sediments from Tasmania, southern mainland Australia, New Zealand and southern South America, inferred the period of 1000 to 1400 CE to be characterized by anomalously dry conditions south of 40°S, implying a positive SAM (Evans et al., 2019; Fletcher et al., 2018; Matley et al., 2020; Moreno et al., 2014). Nevertheless, proxy reconstructions of the SAM based on temperature-sensitive records from tree rings, ice cores, lake sediments and corals spanning the mid-to-polar latitudes show altering positive and negative phases (Figure 2.35).

Prolonged periods of negative SAM values were identified during the period 1400–1700 CE in several reconstructions (Figure 2.35, Abram et al., 2014; Dätwyler et al., 2018; Villalba et al., 2012), with a minimum identified during the 15th century (Hernández et al., 2020), although some disagreements exist between proxy records before 1800 CE (Hessl et al., 2017). Abram et al. (2014) concluded that the mean SAM index during recent decades is at its highest levels for at least the last 1 kyr. Similarly, the summer SAM reconstruction by Dätwyler et al. (2018) indicates a strengthening over the last 60 years that is outside the *very likely* range of the last millennium natural variability. The largest 30- and 50-year trends in the annual SAM index occurred at the end of the 20th century (after 1969 and 1950 respectively), indicating that the recent increase in the SAM is unprecedented in the context of at least the past three centuries (Yang & Xiao, 2018).

Before the mid-1950s, SAM indices derived from station-based datasets, and centennial reanalyses show pronounced interannual and decadal variability but no significant trends, with low correlation between SAM indices due to the diversity across different datasets and sensitivity to the definition used for the index calculation (Barrucand et al., 2018; Lee J. et al., 2019a; Schneider & Fogt, 2018). Various SAM indices exhibit significant positive trends since the 1950s, particularly during austral summer and autumn (Barrucand et al., 2018; Lee J. et al., 2019a; Schneider & Fogt, 2018), unprecedented for austral summer over the last 150 years (Fogt & Marshall, 2020; Jones et al., 2016b). This indicates a strengthening of the surface westerly winds around Antarctica, related to both the position and intensity of the subpolar jet in the SH (IPCC, 2019b; Ivy et al., 2017) (Section 2.3.1.4.3). The SAM trends have slightly weakened after about 2000 (Fogt and Marshall, 2020).

during 1900–2019. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.35 HERE]

In summary, historical station-based reconstructions of the SAM show that there has been a robust positive trend in the SAM index, particularly since 1950 and for the austral summer (*high confidence*). The recent positive trend in the SAM is *likely* unprecedented in at least the past millennium, although *medium confidence* arises due to the differences between proxy records before 1800 CE.

2.4.2 El Niño-Southern Oscillation (ENSO)

AR5 reported with *medium confidence* that ENSO-like variability existed, at least sporadically, during the warm background state of the Pliocene. It was also found (*high confidence*) that ENSO has remained highly variable during the last 7 kyr with no discernible orbital modulation. AR5 concluded that large variability on interannual to decadal timescales, and differences between datasets, precluded robust conclusions on any changes in ENSO during the instrumental period. SROCC reported epochs of strong ENSO variability throughout the Holocene, with no indications of a systematic trend in ENSO amplitude, but with some indication that the ENSO amplitude over 1979–2009 was greater than at any point in the period from 1590–1880 CE. It was also reported that the frequency and intensity of El Niño events in the period from 1951–2000 was high relative to 1901–1950.

Manucharyan and Fedorov (2014) found that ENSO-like variability has been present, at least sporadically, during epochs of millions of years (including the MPWP; Cross-Chapter Box 2.4), with proxy records indicating that this was the case even when cross-Pacific SST gradients were much weaker than present. There is substantial disagreement between proxy records for ENSO activity during the early Holocene (White et al., 2018; Zhang et al., 2014), and for ENSO activity and mean state at the LGM (Ford et al., 2015,2018; Koutavas & Joanides, 2012; Leduc et al., 2009; Sadekov et al., 2013; Tierney et al., 2020; Zhu et al., 2017). A number of studies (Carré et al., 2014; Cobb et al., 2013; Emile-Geay et al., 2016; Grothe et al., 2019; McGregor H. et al., 2013; Thompson et al., 2017; Tian et al., 2017; White et al., 2018) have found that ENSO was substantially weaker than at present at various times in the mid-Holocene within the period from 6 to 3 ka, with stronger decreases in variability revealed by remote proxies than by those close to the core region of ENSO activity. However, Karamperidou et al. (2015) find that weakening in ENSO-related variability in eastern Pacific proxies does not necessarily correspond to weakening in central Pacific proxies. Barrett et al. (2018) concluded that multi-proxy reconstructions are more efficient at identifying eastern Pacific than central Pacific events. This suggests that a weakening of proxy-based signals may indicate an along-equatorial shift in ENSO activity rather than a weakening of ENSO during some periods. Following the period of weak ENSO variability in the mid-Holocene, a number of studies find an increase in ENSO activity which, depending upon the study, commences between 4.4 and 3 ka (Chen et al., 2016; Cobb et al., 2013; Du et al., 2021; Emile-Geay et al., 2016; Koutavas & Joanides, 2012; Thompson et al., 2017; Zhang et al., 2014).

Numerous studies (Hope et al., 2017; Li J. et al., 2013; Liu Y. et al., 2017; McGregor S. et al., 2013; Rustic et al., 2015) find substantial variability in ENSO activity on multi-decadal to centennial timescales over the last 500 to 1 kyr (Figure 2.36). Different proxies show a wide spread in the specific timing and magnitude of events in the pre-instrumental period (e.g. Dätwyler et al., 2019). Most investigators find that ENSO activity in recent decades was higher than the most recent centuries prior to the instrumental period. Grothe et al. (2019) also found that ENSO variance of the last 50 years was 25% higher than the average of the last millennium, and was substantially higher than the average of the mid- to late Holocene. McGregor S. et al., (2010, 2013) looked for common variance changes in pre-existing ENSO proxies, finding stronger ENSO variance for the 30-year period 1979–2009 compared to any 30-year period within the timespan 1590–1880 CE. This finding also holds when adding more recently developed ENSO proxies (Figure 2.36). Koutavas & Joanides (2012), Ledru et al. (2013) and Thompson et al., (2017) identify various periods within the range 1000 BCE to 1300 CE when ENSO activity was greater than in the following centuries, and more

ACCEPTED VERSION SUBJECT TO FINAL EDITS

closely comparable to the mid-20th century onwards behaviour.

[START FIGURE 2.36 HERE]

Figure 2.36: Reconstructed and historical variance ratio of El Niño–Southern Oscillation (ENSO). (a) 30-year running variance of the reconstructed annual mean Niño 3.4 or related indicators from various published reconstructions. (b) variance of June-November Southern Oscillation Index (SOI) and April-March mean Niño 3.4 (1981–2010 base period) along with the mean reconstruction from (a). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.36 HERE]

Since AR5, updates to datasets used widely in prior ENSO assessments resulted in substantial and important revisions to observed tropical Pacific SST data (Section 2.3.1.1). In particular, ERSSTv4, and then ERSSTv5, addressed known SST biases in ERSSTv3 in the equatorial Pacific which affected the derived mean state and amplitude of indices based on that dataset (Huang et al., 2015). During the instrumental period, there is no robust indication of any significant century-scale trend in the east-west SST gradient across the equatorial Pacific Ocean, with periods when gradients have been stronger and weaker than the long-term average on decadal timescales, associated with a predominance of La Niña or El Niño events respectively. The frequency of El Niño and La Niña events is also subject to considerable decadal variability (e.g. Hu et al., 2013) but with no indication of a long-term signal in the frequency of events. The ENSO amplitude since 1950 has increased relative to the 1910–1950 period, as confirmed by independent proxy records (e.g., Gergis & Fowler, 2009), the Southern Oscillation Index (SOI) (Braganza et al., 2009) and SSTs (e.g., Ohba, 2013; Yu & Kim, 2013), although there is a spread between different proxy and instrumental sources as to the magnitude of that increase (Figure 2.36). The El Niño events of 1982–1983, 1997–1998 and 2015–2016 had the strongest anomalies in the Niño 3.4 SST index since 1950. Their predominance was less evident from indices based on de-trended data such as the Oceanic Niño Index (ONI) (which still ranked them as the three strongest events since 1950, but only by a small margin), and in the SOI. Huang B. et al. (2019d) also note that analyses based upon buoy and Argo data, which are only available since the 1990s, are more capable of resolving strong events than analyses which do not include such data.

Prior to the 1950s, SST observations in the tropical Pacific were much sparser and hence uncertainties in Niño indices are much larger (Huang B. et al., 2020). SOI data and some newer SST-based studies show high ENSO amplitude, comparable to the post-1950 period, in the period from the mid-late 19th century to about 1910, but proxy indicators generally indicate that the late 19th and early 20th century were less active than the late 20th century (Figure 2.36). Yu & Kim's (2013) implementation of the ONI found a number of events with the ONI above 1.5°C between 1888 and 1905, then no such events until 1972, whilst the SOI indicates comparable or stronger events to the three strongest post-1950 events in 1896 and 1905. Giese & Ray (2011) also found a number of such events between 1890 and 1920 in the SODA ocean reanalysis, corroborated further by Huang B. et al. (2020a) and Vaccaro et al. (2021), who found that the strength of the 1877–1878 event was comparable with that of the 1982–1983, 1997–1998 and 2015–2016 events. There have also been a number of strong La Niña events (e.g. 1973–1974, 1975–1976 and 2010–2011), with few clear analogues in the 1920–1970 period; the proxy-based analysis of McGregor et al. (2010) indicates that the mid-1970s La Niña period was also extreme in a multi-centennial context. There is no indication that the frequency of high-amplitude events since the 1970s reflects a long-term trend which can be separated from multi-decadal variability, given apparent presence of several high-amplitude events in the late 19th and early 20th centuries, and the relatively large uncertainty in pre-1950 SST data in the tropical Pacific region.

There is a distinction (Annex IV 2.3.1) between El Niño events centred in the eastern Pacific ('Eastern Pacific' (EP) or 'classical' events) and those centred in the Central Pacific ('Central Pacific' (CP) or 'Modoki' events), which have different typical teleconnections (e.g. Ashok et al., 2007; Capotondi et al., 2015; Ratnam et al., 2014; Timmermann et al., 2018). A number of studies, using a range of indicators, have found an increase in recent decades of the fraction of CP El Niño events, particularly after 2000 (Yu and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Kim, 2013; Lübbecke and McPhaden, 2014; Pascolini-Campbell et al., 2015; Jiang and Zhu, 2018). Johnson (2013) found that the frequency of CP El Niño events had increased (although not significantly) over the 1950–2011 period, being accompanied by a significant increase in the frequency of La Niña events with a warm (as opposed to cool) western Pacific warm pool. A coral-based reconstruction starting in 1600 CE (Freund et al., 2019) found that the ratio of CP to EP events in the last 30 years was substantially higher than at any other time over the last 400 years. Variations in the proportion of CP and EP events have also been found in earlier periods, with Carré et al. (Carré et al., 2014) finding a period of high CP activity around 7 ka.

There is no robust indication of any changes in ENSO teleconnections over multi-centennial timescales (Hernández et al., 2020) despite multi-decadal variability. Shi and Wang (2018) found that teleconnections with the broader Asian summer monsoon, including the Indian and the East Asian monsoon, were generally stable since the 17th century during the developing phase of the monsoon, and showed substantial decadal variability, but no clear trend, during the decaying phase. They also found that the weakening of teleconnections between the Indian summer monsoon and ENSO in recent decades had numerous precedents over the last few centuries. Räsänen et al. (2016) also found substantial decadal variability, but little trend, in the strength of the relationship between ENSO and monsoon precipitation in South-East Asia between 1650 and 2000. Dätwyler et al., (2019) identified a number of multi-decadal periods with apparently changed teleconnections at times over the last 400 years.

In the instrumental period, teleconnections associated with ENSO are well known to vary on decadal to multi-decadal timescales (e.g. Ashcroft et al., 2016; He et al., 2013; Jin et al., 2016; Lee & Ha, 2015; Wang Q. et al., 2019). Yun and Timmermann (2018) found that decadal variations in teleconnections between ENSO and the Indian monsoon did not extend beyond what would be expected from a stochastic process. Many observed decadal changes in teleconnections in the instrumental period are consistent with a shift to more central Pacific El Niño events (Evtushevsky et al., 2018; Yeh et al., 2018; Yu & Sun, 2018; Zhao & Wang, 2019). Effects of the PDV (Kwon et al. 2013; Wang S. et al., 2014; Dong et al., 2018) and the AMV (Kayano et al., 2019) can also modulate ENSO teleconnections, and affect the frequency of CP versus EP events (Ashok et al., 2007). Chiodi and Harrison (2015) found that teleconnections over the most recent decades are broadly consistent with those over the last 100 years. Variability in teleconnections can also occur on timescales longer than characteristic PDV timescales (e.g. Gallant et al., 2013).

In summary, there is *medium confidence* that both ENSO amplitude and the frequency of high-magnitude events since 1950 are higher than over the period from 1850 as far back as 1400, but *low confidence* that they are outside the range of variability over periods prior to 1400, or higher than the average of the Holocene as a whole. Overall, there is no indication of a recent sustained shift in ENSO or associated features such as the Walker Circulation, or in teleconnections associated with these, being beyond the range of variability on decadal to millennial timescales. A high proportion of El Niño events in the last 20–30 years has been based in the central, rather than eastern Pacific, but there is *low confidence* that this represents a long-term change.

2.4.3 Indian Ocean Basin and dipole modes

AR5 did not provide an assessment of the Indian Ocean Dipole (IOD) records based on paleo reconstructions. For the instrumental era, AR5 reported that there were no trends in the IOD behaviour. However, the strength of the Indian Ocean Basin-wide (IOB) mode, quantified by the basin-scale averaged SST index, increased in all assessed periods except 1979–2012, but the AR5 neither quantified trends nor provided a confidence statement.

For the LGM, enhanced equatorial Indian Ocean productivity in marine sediment records was associated with strengthened westerly jets, in line with a shallower central-western Indian Ocean thermocline and stronger negative IOD events (Punyu et al., 2014). The LGM Indian Ocean basin was substantially modified by the exposure of the tropical shelves (DiNezio et al., 2018) and this has been associated with an Indian Ocean "El Niño" (Thirumalai et al., 2019). Wurtzel et al. (2018) contend that during the LDT, including the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Younger Dryas event, Indian Ocean precipitation did not mirror the zonal asymmetry observed in Indian Ocean SSTs in the Holocene based upon a speleothem record from Sumatra, but instead reflected shifts in moisture transport pathways and sources. Using Seychelles corals, representing the western pole of the IOD, spanning from the MH to present, Zinke et al. (2014) identified changes in seasonality, with the lowest seasonal SST range in the MH and then again around 2 ka, while the largest seasonal range occurred around 4.6 ka and then again during the near-present (1990–2003). Reconstructions from fossil corals for the eastern Indian Ocean point to stronger negative IOD SST anomalies due to the enhanced upwelling and cooling driven by a stronger monsoon with enhanced anomalous easterly winds in the eastern Indian Ocean during the MH (Abram et al., 2020a). Niedermeyer et al. (2014) from the analysis of stable isotopes in terrestrial plant waxes, suggest that the period 6.5 ka to 4.5 ka was characterized by an anomalously positive IOD mean state. During various parts of the Holocene, periods of a mean positive IOD-like state were associated with increased IOD variability, including events that exceed the magnitude of the strongest events during the instrumental period (Abram et al., 2020b).

From the coral $\delta^{18}O$ record from the Seychelles over 1854–1994, Du et al. (2014) showed a 3–7 year dominant period associated with the IOB in response to ENSO forcing. They identified multi-decadal variability in the IOB, with more active IOB phases during 1870–1890, 1930–1955, and 1975–1992, while decadal variability in the IOB dominated during 1940–1975 (Du Y. et al., 2014). *Evidence* for changes in IOB characteristics during earlier periods (e.g., MH, LGM) is *limited*.

The role of decadal to multi-decadal variability has recently emerged as an important aspect of the IOD with many indications of the effects of Pacific Ocean processes on IOD variability through atmospheric and oceanic mechanisms (Dong et al., 2016; Jin et al., 2018; Krishnamurthy & Krishnamurthy, 2016; Zhou et al., 2017). Positive events in the 1960s and 1990s were linked to a relatively shallow eastern Indian Ocean thermocline, and a primarily negative IOD state in the 1970s and 1980s was related to a deeper thermocline (Ummenhofer et al., 2016). Positive IOD events may have increased in frequency during the second half of the 20th century (Abram et al., 2020a,b). Earlier observations of apparent changes in the frequency and / or magnitude of the IOD events are considered unreliable, particularly prior to the 1960s (Hernández et al., 2020). Although the seasonal evolution and the type of ENSO (Section 2.4.2) may influence the character of the IOD (Guo et al., 2015; Zhang et al., 2015; Fan et al., 2016), the occurrence of some IOD events may be independent of ENSO (Sun et al., 2015).

To summarize, there is *low confidence* in any multi-decadal IOD variability trend in the instrumental period due to data uncertainty especially before the 1960s. In addition to data uncertainty, understanding of the IOB variability during the instrumental period is also limited by large-scale warming of the Indian Ocean. Neither the IOD nor the IOB have exhibited behaviour outside the range implied by proxy records (*low confidence*).

[START FIGURE 2.37 HERE]

Figure 2.37: Indices of interannual climate variability from 1950–2019 based upon several sea surface temperature based data products. Shown are the following indices from top to bottom: IOB mode, IOD, Niño4, AMM and AZM. All indices are based on area-averaged annual data (see Technical Annex IV). Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.37 HERE]

2.4.4 Atlantic Meridional and Zonal Modes

AR5 reported no changes in the Atlantic Meridional Mode (AMM) during the 20th century or shorter periods thereof. For the Atlantic Zonal Mode (AZM), also referred as the Atlantic Niño, the AR5 reported increases during the 1950–2012 period but neither assessed trends nor provided a confidence statement. The AR5 did not assess paleo evidence for the AZM and AMM.

Paleo-reconstructions of these two modes remain rather limited. Nonetheless, the interhemispheric cross-

ACCEPTED VERSION SUBJECT TO FINAL EDITS

equatorial SST gradients linked to changes in ITCZ locations characteristic of the AMM has been found during the LGM, Heinrich Stadial 1 and the MH, with the largest shift occurring during HS1 (McGee et al., 2014). Similarly, the dipole-like SST pattern in the South Atlantic subtropics, which is related to the AZM (Foltz et al., 2019; Lübbecke et al., 2018; Morioka et al., 2011; Nnamchi et al., 2016, 2017; Rouault et al., 2018; Venegas et al., 1996), has been reconstructed using SST proxies from marine sediment cores during the past 12 kyr (Wainer et al., 2014). The reconstructed index captures two significant cold events that occurred during the 12.9–11.6 ka and 8.6–8.0 ka periods in the South Atlantic (Wainer et al., 2014).

During the observational period the AZM and AMM (Figure 2.37) are related to the AMV largely controlling the interhemispheric gradient of the SST at decadal to multi-decadal timescales (Li et al., 2015; Lübbecke et al., 2018; Polo et al., 2013; Svendsen et al., 2014; Tokinaga & Xie, 2011). The AZM interannual variability is enhanced (Foltz et al., 2019; Lübbecke et al., 2018), and is more strongly related to ENSO during the negative phase of the AMV (Martín-Rey et al., 2014, 2018; Polo et al., 2015; Nnamchi et al., 2020). The AZM displayed a persistent weakened variability over the 1960–2009 period associated with declined cold tongue upwelling (Tokinaga and Xie, 2011), which became pronounced since 2000 (Prigent et al., 2020a,b). Despite these multi-decadal fluctuations, there is *limited evidence* for any sustained change in the AMM (Chang et al., 2011; Martín-Rey et al., 2018) and AZM (Martín-Rey et al., 2018; Nnamchi et al., 2020) during the instrumental period. The AZM and AMM interact on interannual timescales (Foltz & McPhaden, 2010; Pottapinjara et al., 2019; Servain et al., 1999) leading in 2009 to extremes of both modes in which the negative phase of the AMM (Burmeister et al., 2016) (Foltz et al., 2012) preceded an equatorial cold tongue cold event that was unprecedented in the prior 30 years (Burmeister et al., 2016; Foltz & McPhaden, 2010).

In summary, *confidence* is *low* in any sustained changes to the AZM and AMM variability in instrumental observations. There is *very low confidence* in changes of the paleo AZM and AMM due to extremely limited availability of paleo reconstructions.

2.4.5 Pacific Decadal Variability

Pacific Decadal Variability (PDV) refers to the ocean-atmosphere climate variability over the Pacific Ocean at decadal-to-interdecadal time scales and is usually described by the Pacific Decadal Oscillation (PDO) or the Interdecadal Pacific Oscillation (IPO) indices. AR5 and SROCC reported a large shift of the PDO in the late 1970s, with a predominantly positive phase until the end of the 1990s, being mainly negative afterwards. There was no significant change assessed in the PDO during the instrumental period as a whole, and no confidence level was assigned. Changes in the pre-instrumental era PDO were not assessed in AR5.

The existence of the PDV in the centuries prior to the instrumental period is evidenced by a variety of proxy records based on tree rings (Biondi et al., 2001; D'Arrigo and Ummenhofer, 2015), corals (Deng et al., 2013; Felis et al., 2010; Linsley et al., 2015) and sediments (Lapointe et al., 2017; O'Mara et al., 2019). There is little coherence between the various paleo-proxy indices prior to the instrumental record, and neither these nor the instrumental records provide indications of a clearly defined spectral peak (Buckley et al., 2019; Chen & Wallace, 2015; Henley, 2017; Newman M. et al., 2016; Zhang L. et al., 2018). For instance, spectral analysis from millennia length PDV reconstructions shows spectral peaks at multi-decadal, centennial and bi-centennial time scales (Beaufort and Grelaud, 2017), while only multi-decadal oscillations can be detected in the shorter (less than 400 years into the past) paleoclimate reconstructions. A variety of proxies suggest a shift in the PDV from the early-mid Holocene, which was characterized by a persistently negative phase of the PDO (i.e. weak Aleutian Low), to the late Holocene, and a more variable and more positive PDO (i.e. strong Aleutian Low) conditions. This shift at around 4.5 ka is also evident in the PDO periodicities, changing from bidecadal and pentadecadal variability in the early Holocene to only pentadecadal periodicities in the late Holocene (Hernández et al., 2020). Several proxy records indicate that the strengthening in the Aleutian Low inferred since the late 17th century is unprecedented over the last millennium (Liu Z. et al., 2017; Osterberg et al., 2017; Winski et al., 2017), in line with an increase in PDV low-frequency variability (Hernández et al., 2020; Williams et al., 2017).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

The PDO and IPO indices are significantly correlated during the instrumental period, showing regime shifts in the 1920s, 1940s, 1970s and around 1999. Positive PDV phases were observed from the 1920s to the mid-1940s and from the late 1970s to the late 1990s, while negative phases occurred from mid-1940s until the late 1970s, and since 1999 (Figure 2.38; Han et al., 2013; Chen and Wallace, 2015; Newman M. et al., 2016). The associated spatial patterns are quite similar, but the PDO pattern exhibits stronger SST anomalies in the extra-tropical North Pacific than the IPO (Chen & Wallace, 2015). The strength and structure of the SST patterns also differ among the periods (Newman M. et al., 2016).

[START FIGURE 2.38 HERE]

Figure 2.38: Indices of multi-decadal climate variability from 1854–2019 based upon several sea surface temperature based data products. Shown are the indices of the AMV and PDV based on area averages for the regions indicated in Technical Annex IV. Further details on data sources and processing are available in the chapter data table (Table 2.SM.1).

[END FIGURE 2.38 HERE]

Instrumental observations are sparse prior to 1950, and thus the fidelity of any PDV index derived for the second part of the 19th century and early decades of the 1900s is relatively low (Deng et al., 2013; Wen et al., 2014) (Figure 2.38). This results in *low agreement* in the classification of the PDO / IPO phase among several indices, even during recent years with the availability of high-quality data. Nevertheless, the teleconnection patterns are robust regardless of the index used to characterize the PDO (McAfee, 2017). Analysis of time series of PDO and IPO highlights the (multi-) decadal nature of this mode of variability with no significant trends, but highlights a recent switch from a positive to a negative phase since 1999 / 2000 across all indicators (England et al., 2014; Henley, 2017).

In summary, the PDV in the instrumental record is dominated by (multi-) decadal-scale shifts between positive and negative phases over the last 150 years with no overall trend (*high confidence*). There is *low confidence* in paleo-PDV reconstructions due to discrepancies among the various available time series in terms of phasing and timing. However, there is *high confidence* in the occurrence of a shift from predominantly negative to positive PDO conditions from the middle to the late Holocene.

2.4.6 Atlantic Multidecadal Variability

AR5 reported no robust changes in Atlantic Multidecadal Variability (AMV) reconstructions based on paleo records due to low consistency between different AMV reconstructions prior to 1900. AR5 concluded that there have been no significant trends in the AMV index during the instrumental period and there was difficulty in interpreting the AMV signal because of the long-term underlying SST warming trend.

The AR5 conclusions about large uncertainties in AMV paleo reconstructions (Hernández et al., 2020) have been reinforced by recent studies of tree rings (Wang et al., 2017b), Greenland ice (Chylek et al., 2012), and corals (Kilbourne et al., 2014; Svendsen et al., 2014a; Wang et al., 2017b). The AMV exhibited a generally positive state over the first millennium of the CE (Mann et al., 2009; Singh et al., 2018). Paleo reconstructions over the last millennium consistently show a negative AMV phase during 1400–1850 CE and a positive phase during 900–1200 CE (Mann et al., 2009; Singh et al., 2018; Wang J. et al., 2017), consistent with warmer surface temperatures from tropical Atlantic records (Kilbourne et al., 2014).

Instrumental observations show that AMV is characterized by basin-wide warm and cool periods with an average variation in SST of about 0.4°C, but with larger variations in the North Atlantic subpolar gyre. Despite small differences in indices used to define the AMV (Annex IV), they all show warm periods occurring approximately between 1880–1900, 1940–1960, and from the mid-1990s to present, with cool periods in between (Figure 2.38) but no overall sustained change during the instrumental period (Bellomo et

ACCEPTED VERSION SUBJECT TO FINAL EDITS

al., 2018; Booth et al., 2012; Gulev et al., 2013; Sun et al., 2017).

The oceanic changes are seen in salinity and temperature variations over the upper 3000 m of the North Atlantic (Polyakov et al., 2005; Keenlyside et al., 2015), and in sea level variations in the Western North Atlantic along the Gulf Stream passage (McCarthy et al., 2015). The pattern and strength of the AMV differs among the periods (e.g., Svendsen et al., 2014a; Reynolds et al., 2018) and there are indications that there may have been a shift since 2005 toward a negative phase of the AMV (Robson et al., 2016).

In summary, no sustained change in AMV indices has been observed over the instrumental period (*high confidence*). However, instrumental records may not be long enough to distinguish any oscillatory behaviour from trends in the AMV. There is *low confidence* in the paleo AMV reconstructions due to a paucity of high-resolution records.

2.5 Final remarks

The assessment in this chapter is based upon an ever-expanding volume of available proxy and observational records and a growing body of literature. Since AR5, improvements have been made in all aspects of data collection, data curation, data provision and data analysis permitting improved scientific insights. The chapter has also benefitted from the availability of new products from a range of emerging, mainly space-based, observing capabilities and new generations of reanalysis products. However, a number of key challenges still remain which, if addressed, would serve to strengthen future reports.

- Development of new techniques and exploitation of existing and new proxy sources may help address challenges around the low temporal resolution of most paleoclimate proxy records, particularly prior to the Common Era, and ambiguities around converting paleoclimate proxy data into estimates of climate-relevant variables. Conversions rely upon important proxy-specific assumptions and biases can be large due to limited accounting of seasonality, non-climatic effects, or the influence of multiple climate variables. These challenges currently limit the ability to ascertain the historical unusualness of recent directly observed climate changes for many indicators. {2.2, 2.3}

- Improved sharing of historical instrumental and proxy records (including metadata) along with significant efforts at data rescue of presently undigitised records would serve to significantly strengthen many aspects of the present assessment. Longer observational time series help to better understand variability, and any underlying periodicity in climate indicators and climate forcers, especially for components of the climate system where the dominant response is on multi-decadal and longer time scales. Targeted rescue of early marine data records, especially from waters of the tropical oceans and the Southern Ocean could help constrain modes of variability and important teleconnection changes in, for example, the hydrological cycle and patterns of global temperature change. {2.2, 2.3, 2.4}

- Contemporary observing systems have limitations in parts of the Earth system with limited accessibility or coverage, for example coastal and shallow ocean, polar regions, marine biosphere, and the deep sea, leading to seasonal-dependency and regional variability in data coverage and uncertainty which serve to limit confidence in the present assessment of changes. {2.3}

- Contradictory lines of evidence exist between observations and models on the relationship between the rates of warming in GMST and GSAT, compounded by limitations in theoretical understanding. Improvements in air temperature datasets over the ocean and an improved understanding of the representation of the lowermost atmosphere over the ocean in models would reduce uncertainty in assessed changes in GSAT. {Cross-Chapter Box 2.3}

Frequently asked questions

FAQ 2.1: The Earth's temperature has varied before. How is the current warming any different?

Earth's climate has always changed naturally, but both the global extent and rate of recent warming are unusual. The recent warming has reversed a slow, long-term cooling trend, and research indicates that global surface temperature is higher now than it has been for millennia.

While climate can be characterised by many variables, temperature is a key indicator of the overall climate state, and global surface temperature is fundamental to characterising and understanding global climate change, including Earth's energy budget. A rich variety of geological evidence shows that temperature has changed throughout Earth's history. A variety of natural archives from around the planet, such as ocean and lake sediments, glacier ice and tree rings, shows that there were times in the past when the planet was cooler, and times when it was warmer. While our confidence in quantifying large-scale temperature changes generally decreases the farther back in time we look, scientists can still identify at least four major differences between the recent warming and those of the past.

It's warming almost everywhere. During decades and centuries of the past 2000 years, some regions warmed more than the global average while, at the same time, other regions cooled. For example, between the 10th and 13th centuries, the North Atlantic region warmed more than many other regions. In contrast, the pattern of recent surface warming is globally more uniform than for other decadal to centennial climate fluctuations over at least the past two millennia.

It's warming rapidly. Over the past 2 million years, Earth's climate has fluctuated between relatively warm interglacial periods and cooler glacial periods, when ice sheets grew over vast areas of the northern continents. Intervals of rapid warming coincided with the collapse of major ice sheets, heralding interglacial periods such as the present Holocene Epoch, which began about 12,000 years ago. During the shift from the last glacial period to the current interglacial, the total temperature increase was about 5°C. That change took about 5000 years, with a maximum warming rate of about 1.5°C per thousand years, although the transition was not smooth. In contrast, Earth's surface has warmed approximately 1.1°C since 1850–1900. However, even the best reconstruction of global surface temperature during the last deglacial period is too coarsely resolved for direct comparison with a period as short as the past 150 years. But for the past 2000 years, we have higher-resolution records that show that the rate of global warming during the last 50 years has exceeded the rate of any other 50-year period.

Recent warming reversed a long-term global cooling trend. Following the last major glacial period, global surface temperature peaked by around 6500 years ago, then slowly cooled. The long-term cooling trend was punctuated by warmer decades and centuries. These fluctuations were minor compared with the persistent and prominent warming that began in the mid-19th century when the millennial-scale cooling trend was reversed.

It's been a long time since it's been this warm. Averaged over the globe, surface temperatures of the past decade were probably warmer than when the long cooling trend began around 6500 years ago. If so, we need to look back to at least the previous interglacial period, around 125,000 years ago, to find evidence for multi-centennial global surface temperatures that were warmer than now.

Previous temperature fluctuations were caused by large-scale natural processes, while the current warming is largely due to human causes (see, for example, FAQ 1.3, FAQ 3.1). But understanding how and why temperatures have changed in the past is critical for understanding the current warming and how human and natural influences will interact to determine what happens in the future. Studying past climate changes also makes it clear that, unlike previous climate changes, the effects of recent warming are occurring on top of stresses that make humans and nature vulnerable to changes in ways that they have never before experienced (for example, see FAQ 11.2, FAQ12.3).

[END FAQ 2.1, FIGURE 1 HERE]

FAQ 2.2: What is the evidence for climate change?

The evidence for climate change rests on more than just increasing surface temperatures. A broad range of indicators collectively leads to the inescapable conclusion that we are witnessing rapid changes to many aspects of our global climate. We are seeing changes in the atmosphere, ocean, cryosphere, and biosphere. Our scientific understanding depicts a coherent picture of a warming world.

We have long observed our changing climate. From the earliest scientists taking meteorological observations in the 16th and 17th centuries to the present, we have seen a revolution in our ability to observe and diagnose our changing climate. Today we can observe diverse aspects of our climate system from space, from aircraft and weather balloons, using a range of ground-based observing technologies, and using instruments that can measure to great depths in the ocean.

Observed changes in key indicators point to warming over land areas. Global surface temperature over land has increased since the late 19th century, and changes are apparent in a variety of societally relevant temperature extremes. Since the mid-1950s the troposphere (i.e., the lowest 6–10 km of the atmosphere) has warmed, and precipitation over land has increased. Near-surface specific humidity (i.e., water vapour) over land has increased since at least the 1970s. Aspects of atmospheric circulation have also evolved since the mid-20th century, including a poleward shift of mid-latitude storm tracks.

Changes in the global ocean point to warming as well. Global average sea surface temperature has increased since the late 19th century. The heat content of the global ocean has increased since the 19th century, with more than 90% of the excess energy accumulated in the climate system being stored in the ocean. This ocean warming has caused ocean waters to expand, which has contributed to the increase in global sea level in the past century. The relative acidity of the ocean has also increased since the early 20th century, caused by the uptake of carbon dioxide from the atmosphere, and oxygen loss is evident in the upper ocean since the 1970s.

Significant changes are also evident over the cryosphere – the portion of the Earth where water is seasonally or continuously frozen as snow or ice. There have been decreases in Arctic sea ice area and thickness and changes in Antarctic sea ice extent since the mid-1970s. Spring snow cover in the Northern Hemisphere has decreased since the late-1970s, along with an observed warming and thawing of permafrost (perennially frozen ground). The Greenland and Antarctic ice sheets are shrinking, as are the vast majority of glaciers worldwide, contributing strongly to the observed sea level rise.

Many aspects of the biosphere are also changing. Over the last century, long-term ecological surveys show that many land species have generally moved poleward and to higher elevations. There have been increases in green leaf area and/or mass (i.e., global greenness) since the early 1980s, and the length of the growing season has increased over much of the extratropical Northern Hemisphere since at least the mid-20th century. There is also strong evidence that various phenological metrics (such as the timing of fish migrations) for many marine species have changed in the last half century.

Change is apparent across many components of the climate system. It has been observed using a very broad range of techniques and analysed independently by numerous groups around the world. The changes are consistent in pointing to a climate system that has undergone rapid warming since the industrial revolution.
